CLINICAL LESSONS.

The Treatment of Sciatica.

BY S. WEIR MITCHELL, M.D.,
OF PHILADELPHIA.

[Reported by J. M. TAYLOR, M.D., Assistant Physician to the Infirmary for Diseases of the Nervous System.]

I PROMISED that these clinical lessons should sometimes consider for you such peculiar therapeutic methods as are in use within our walls. Accordingly, I call your attention to-day to certain points in the diagnosis and treatment of sciatica.

Under this name the books include true neuralgia, without demonstrable organic changes in the nerve, and the graver pain which is due always, as a rule, to some grade of neuritis.

Let us admit that the first class is seen in practice in all degrees, has a great variety of parentage, and at times many parents, or haply none that can be found.

To men like you, advanced students, clinically watchful, it is needless to say that the milder sciatic neuralgias are sometimes of malarial, gouty, rheumatic, syphilitic, anæmic, or other origin, mere functional disorders like the typical fifth-nerve neuralgia. Be this as it may, I am sure that more often than elsewhere these pains, whatever be their cause, are likely to become permanent and to pass into distinct forms of organic disease of the sheaths, and, at last, as remoter possibilities, into neuritis, with degenerative changes in the nerve-tissue. Too often you can detect no distinct cause, or find that you must fall back for explanation on a general lowering of tone, or on relatively slight anæmia, or something as trivial in appearance. The strange causes, the reflex visceral parentages, the lucky decayed tooth, etc., are, alas! too rare, but serve at best to keep us watchful and to make the text-books less dull reading by introducing the pleasant unexpectedness of romance.

I pause here to urge on you the fact that every human being has a different standard of resistance to the effects of anæmia, malaria, or any of the varied forms of blood-defect or mal-assimilation. What does not depress one is serious for another. Also I ask you again to remember that frequently a neuralgia has many parents. Over-work, over-worry, or a hemorrhage may cause anæmia, and out of this may come functional gastro-intestinal failures, and these in turn may occasion lithæmic disturbances, or make available for mischief the effects of exposure or accident.

Possibly, at times, old and long latent syphilis is answerable. Such a case meets with a fall on the buttocks, and thus acquires, owing to the constitutional poisoning of the patient, capacities to develop an obstinate neuritis. The type and severity depend upon the hygienic surroundings and the past history. An English writer declares that he has never seen causalgia such as we saw from 1861 to 1864, nor have I so seen it since, because men worn out with marching, soaked with malaria, or exhausted with exposure and diarrhœa are not now the subjects of wounds from minie-balls.

For the unthoughtful there is only the final accident, for the man who thinks there is link on link of the chain of preparatory states, and it were easy to illustrate them further. This is, however, to be only a lecture of hints, and I pass on.

Before considering the ordinary sciaticas I pause to say a word as to sciatic pain of which the cause is organic and lies within the pelvis. You cannot be too watchful as to this source of trouble. When you find extravagant pain down the nerve, be careful how you decide. Sciatic neuritis is a very painful malady, but the pain caused by the squeeze and inflammation of rapid intra-pelvic carcinoma is a far more terrible thing, and the grade of pain may help you in your decision. In any case of doubt, the rectal examination should be thorough.

Several times in my life I have seen the causal diagnosis of a furious sciatica made on the post-mortem table, by the discovery of a saddle-like growth astride of the cords of the parent plexus. If the tumor be small, palpation is useless as a guide, and the best of us may be baffled. At times a large growth rewards our search. Twice I have seen accumulations of fæces sufficient to give rise to irritative pressure; one got well, but one, which had been treated for multiform malignant tumors, was so regarded up to death and perished miserably. The post-mortem section showed enormous fæcal accumulations of a hardness such as caused one of the assistants to think they were masses of calculi. In this case the pain was in the right sciatic nerve.

Benign tumors or growths of syphilitic origin may act within the pelvis to cause sciatic pain, as the following interesting case serves to show.

L. B., forty years of age, a planter, states that sixteen years ago he had a sore, then said to be syphilitic. He has had no secondaries of which he was ever aware, but has all his life been subject to herpetic eruptions on the glans penis. He has been, over and over, pronounced to be free from specific disease. In August, 1891, he began to have vague aches in the occiput, the right knee, and the thigh. In September, he had pain in and about the sciatic notch and down the leg. These aches became worse, especially below the knee, and at last almost deprived him of power to stand or walk. At night, after twelve, his pain was so intense that morphine became essential. His case on entry here was too easily taken for granted by me as an ordinary neuritis, and subjected to the usual treatment. When this entirely failed, I began to suspect that we were dealing with sciatica of an unusual type. In making the re-examination which this suspicion caused me to undertake, I found at the middle of the right thigh a smooth swelling of the bone. If, as seemed likely, this was a node and specific, it became clear that it was in no way competent to cause the pain. But it was as clear that there might be within the pelvis or at the notch a similar growth, so placed as to compress and irritate the great sciatic. One week of full treatment by iodides led to rapid lessening of the external node and to a swift extinction of the pain. After a few weeks he was dismissed cured.

It is also well to know that childbed may cause sciatica. I knew many years ago of one woman who always suffered from two to three weeks after labor with double sciatic pain, and at last, after a labor in which there was profuse flooding, she was afflicted with a left-side sciatica for many months. Some pain in these nerves you will all hear about in childbeds, and I may add that to strain at stool may cause increase of suffering to a patient tormented by sciatica, and even to rheumatic people who are without distinct neuritis.

Of the terrible sciatica of alcohol I need say nothing here, and that lead or arsenic may cause sciatic neuralgia of neuritic type is also to be remembered.

Strange as it may seem, one may be misled for a time as to diagnosis by a subacute inflammation of the hip-joint with aches about the knee, slight wasting, and stiffness. As between this and the sciatic pain which exists chiefly in and around the foramen of exit and has caused nutritive changes in the gluteal muscles, one may at times be troubled. At all events I have seen surgeon and physician err one way or another as to these maladies.

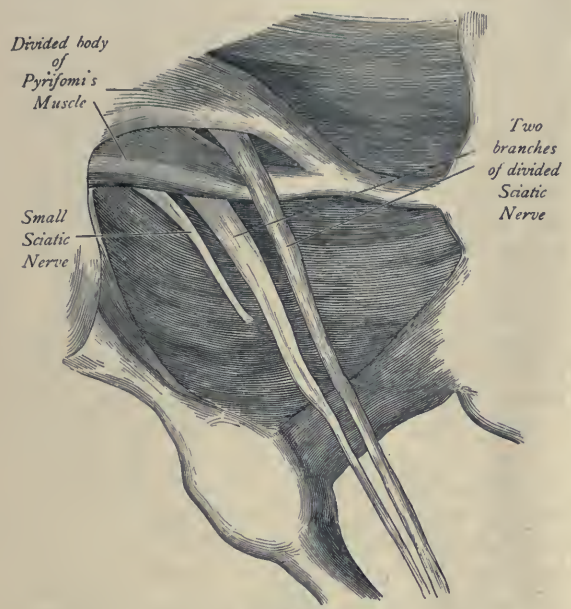
And now as to one or two matters connected with sciatic pain, before we consider the treatment of sciatic neuritis and the neuralgias likely, under conditions adverse to recovery, to eventuate in the more serious malady. I shall presume upon your full knowledge of the symptoms of sciatica. The gait, the wasting, the pain-points, and the hyperæsthesia or anæsthesia I may pass over as familiar. But look now at the case I show you from McCormick Ward. When this man entered here he had violent pain at the sciatic notch on carrying the leg forward. A case near by, now well, had pain down the leg on putting the leg far back, and at each step as the leg on which he stood was at its extreme limit of backward position. The forward swing eased him. A case seen last year fell as if shot when he stood on the lame leg, the pain darting down the limb from the notch. A few years ago I saw a still worse example of this form of pain. In this latter case, after long treatment, I found that very deep pressure at or over the notch caused acute pain. Finally, we cut down (I think it was Dr. Morton who operated) and found a small, round, hard, fibrous growth just over the point of exit of the nerve. Its removal brought about a speedy recovery. To fully extend the leg in sciatica always gives increase of pain, and some sciatic patients carefully limit the length of their step so as not to make any pull on the nerve.

Walking exercise usually makes the pain of sciatic neuritis worse. The cause is, perhaps, not as simple as it may seem to you. Of course, it is natural to presume—is, I think, generally taken for granted—that the rhythmic tension of the muscles at the notch squeezes a swollen nerve as we walk or stand, and so increases the pain.

I have taken some pains to see how far this may be true. The result of a brief study of dissections made for me by Dr. Addinell Hewson, that I might investigate the matter, proved of interest, especially as the anatomies did not make it entirely clear.

The great sciatic emerges from its foramen with ample space around it. Then it lies in an irregular triangular gutter between the tuber ischii and the great and lesser trochanters. This space is over-large and narrows or widens as inversion or eversion of the foot and leg turns the head of the bone inward or outward. Above or posteriorly, this deep gutter is covered by the gluteus maximus. At the lower edge of this muscle the deep fascia turns under it and then is reflected downward, so as to roof over the lower part of the sciatic gutter with dense covering, which is attached to the ischial tuberosity and to a part of the lesser trochanter. This fascia thus forms a strong tentorium, protecting the nerve more or less from external violence. The pyriform muscle, which overlies the nerve, is so situated that it crosses where the nerve, lying rather free in its notch, could, even if swollen, with difficulty suffer from the action of this muscle. In front of the nerve lie the quadratus and gemelli and the tendon of the obturator. When these muscles swell in such contractile effort as everts the foot, they may more or less press upon

the nerve, but the consentaneous action of the tightening mass of the gluteus must tend to enlarge the cavity in front of it and make tense its roof, so that unless immense swelling of the nerve be present the activity of these muscles could scarcely cause pinching or pressure of moment.



Anomalous high division of great sciatic nerve, one branch passing through pyriformis muscle.

Dr. J. M. Taylor called my attention to the fact that in 1600 sciatic nerves there were 49 anomalies of a nature to quite surely cause pain in a swollen nerve when the pyriformis acts. In these anomalies the nerve divides so that one part goes through the belly of the muscle—as is well seen in Dr. Taylor's sketch. As a fact, eversion or inversion of the foot rarely gives rise to increase of sciatic ache. We must look elsewhere for explanations. It seems to me probable that the forward swing of the leg in walking may be felt because at its full limit it must repeatedly stretch the nerve a little, and very little is needed to hurt an inflamed nerve. Thus, going up stairs, which stretches the nerve far more, is painful. Also, we should remember that the thigh muscles, bound down by tense fascia, must in action somewhat compress the nerve.

Whether the exceptional cases of violent anguish referred to the notch on standing are due or not to the anomalous peculiarity mentioned I cannot say.

Very rarely, it is the backward motion which causes pain, and for this I can see no explanation.

I suspect that very often the pain increased or reproduced by walking is due to more mysterious causes, which are of central origin and analagous to such as are present in facial neuralgias, when the patient chews or swallows, talks or laughs. Then there seems to arise a sudden reinforcement of capacity to feel pain on the part of the nerve-centers. It is also quite sure that certain sciatic cases are eased by exertion; probably these are not cases of neuritis.

I wish to say a few words as to the time of the exacerbations of pain in sciatica. I have studied with some care the hour of greatest pain in neuralgias, and I think I may be secure in stating that for fifth-nerve neuralgias it is likely to be before noon, and for sciatica, after 4 P.M. In many cases it is between 12 at night and 4 A.M.; these figures are the results of an examination of something like a hundred neuralgias.

Whilst this holds good for our climate, it may be quite untrue elsewhere, as in the South or in England. I mention this, because abroad the remarkable statistics of my clinics, as to chorea and our seasons, and of Dr. Morris Lewis's admirable studies, both of chorea and of rheumatism in relation to seasons, have been doubted, or described as not having been confirmed by European observers. It would be odd enough if they were, as almost inevitably the relation of pain or other morbid phenomenon to time of day, or year, must differ in one continent from another, and it is the comparative results which become interesting.

As regards this question of the time of pain-occurrence there are valuable papers by myself[1] and by Captain Catlin,[2] U. S. A., which exhibit, as concerns a remarkable case of traumatic neuralgia, a curious tendency to concentrate pain at set periods of the day.

Sciatic pain tends to be worse at night. The treatment should, so to speak, follow it into this period; and this is why I have so insisted here on the time-question.

And now, let us pass on to the treatment. If you turn to the text-books, as to this and other well-studied diseases, you will find a bewildering list of drugs, and mechanical and other treatment mentioned with the constant introduction "So-and-so has been or may be used"; also, "G recommends this, K that, in this disorder." Dropping all this puzzling list of drugs, and what not, I shall now tell you what I usually do here, and do *in succession* in these cases, as improvement or failure makes desirable. In private practice you cannot always do at once as you wish to do, or think really best. Except as to that which money brings—change of climate and the

[1] "Relation of Pains to Weather," by S. Weir Mitchell, M.D. Amer. Journ. Med. Sciences, April, 1877.

[2] "Relations of Pain to Weather, Studied during Eleven Years of a Case of Traumatic Neuralgia," by Captain R. A. Catlin, U.S A., with Notes by S. Weir Mitchell. Transactions of the College of Physicians, Philadelphia, 1883.

Memoirs of Nat. Acad. Sci., 1892. Final report by Capt. Catlin.

like—and as far as mere immediate treatment is concerned, the poor, in a hospital like this, have sometimes a better chance than the rich or highly placed, as certain illustrious precedents may prove.

If in the text-books the list of drugs and counter-irritants were followed by a clear statement of what the author advised in mild or in grave cases, these books would acquire a definite and individualized value. One may read all that Gowers, or Gray, or Dana says, and, if young in practice, rise without the least distinct idea as to just how these men treat their own cases of sciatica. You may rest assured that they are more definite in their practice than might be inferred from their books. The treatises on mere therapeutics are yet worse. In one is a list of forty agents which may be used in sciatica.

Let us say we have to deal with a mild case, a first attack. The usual careful search through the organs and secretions has been made. Any obvious constitutional disorder is provided for. What next? As to this, all are at one—rest in bed, constant and prolonged till recovery is assured. Few things are as valuable as dry cups, if you use them thoroughly and early. Very effective is a double or even a triple row of cups all around and over the notch and down the leg, along the nerve-branches to the ankle. There should be some three dozen cups simultaneously applied, and they should remain on half an hour, but not blister. This measure is repeated the next day; then two days later, and this alone may answer. Or, if for any reason you cannot do this, put on mustard, at least three inches wide, from notch to ankle; or, at least, to the knee. Add a little molasses to the mustard, and you can then leave it on for hours; and this, too, may answer. Some of the elder doctors, like Pearson, knew the fact that very extensive moderate counter-irritation is often better than limited and more severe attacks on the skin by irritants.

If these means fail, what is to be done next? As to this I hesitate no longer, but go on at once to the means I now employ in chronic cases. But, at the beginning, and perhaps later, until you can permanently ease the ache, it is needful sometimes to use narcotics. Cocaine is the best, in from one-fourth to one-half grain hypodermatic injections. How rarely we use narcotics here, even in our worst cases of sciatica, the resident physicians very well know. If you prefer morphine, give one dose at about 8 or 9 P.M., and get rid of it soon.

But suppose the disease intractable? Let us take the case in which mild irritants, rest in bed, and constitutional means have failed; or that of the old hospital guest who has carried pain with him from ward to ward this year or two.

Consider a moment the attitude and ways of a really severe case of neuritis, and let us see what guides these obviously offer. The man lies in bed with the leg slightly bent at the knee and hip. If he wishes to turn, he keeps the limb rigid—splints it, let us say, by the use of his muscles, aids it with the stay of supporting hands. Also in the exacerbations, in the anguish of the night's increase of pain, a touch, even slight friction of the bedclothes, increases the distress. It was while watching such a case that it occurred to me to use a splint to keep the limb quiet. If I could by this means forbid the use of muscles, I should thus far secure to the nerve physiologic rest, which, for many reasons, seemed desirable. If *free* motion gave pain, *all* motion might be relatively hostile to recovery. At a much later date I was struck with the familiar fact that contacts—sudden, rough touch, as of the bedclothes—were able to increase the pain in certain cases. It seemed to me as I considered the matter that all contacts might be hurtful, and that by a bandage I could secure the surfaces from these, and thus still further insure to the nerve functional repose. Finally, it was possible that the bandage might, by gentle, firm, general pressure, lessen the amount of blood circulating in the leg, and thus ease, just as one eases an aching finger by firmly grasping it. My success seems to be a justification of the reasoning; but that is of little moment. There is much good treatment we cannot explain.

There are many ways of doing these two things. But whether you suspend the leg in a splint, or use wire or moulded splints, the splint must check motion at the hip and knee. This is the essential matter. The bandage must be pure flannel, and reach from foot to groin. I have used rubber or elastic stockings, and also combined the splint with pressure by plaster or other splint dressings. Practically here we use for all true sciaticas a firm bandage from foot to groin and reapply it twice a day. The leg is slightly bent at the knee, and kept extended at the thigh, and in this position secured to a light side-splint from axilla to ankle by a few turns of a bandage. Care is, of course, taken to prevent pressure on the heel. After a few days the joint-angles are slightly changed at each dressing. Still later, as the pain fades, the joints are mildly and passively exercised whenever the bandages are renewed. Usually three weeks must pass before we can begin to abandon treatment; a much longer time may be needed for old cases. Finally, we take off the splint *in the day* but leave the bandage on. At night we replace the splint. Later we give up the splint and, with the presence or absence of pain as our sole guide, in like manner we omit the bandage, now in the day, and finally at night, but not at all until the patient has begun to move about, and perhaps not then.

Meanwhile with cod-liver oil, iron at need, good diet, care as to the bowels, never allowing a costive

passage, forbidding effort at stool (preventing it by hot enemas)—by these means, I repeat, we carry the man through. When the pain has quite gone we use mild massage once a day before replacing the bandages. The process must be careful, with avoidance of roughness.

There may be left, near the close of this treatment, one or more points of persistent pain, not often severe. These are best treated by counter-irritants, the best being the light touch of a white-hot Paquelin button, or a small blister.

The getting up of a severe sciatic case is not unimportant. Motion, the full use of the leg and buttock muscles, and the pressure of the hard edge of a chair, or close stool, are likely to bring back pain. Hence, *we do not allow a man to sit at all the first week* that he is up. He must at first stand, and then walk, but always, whether he walk or stand, it must be with the aid of crutches. He may be upright, on a bed, but not seated. Electricity is rarely needed, even if there has been much wasting. With exercise and massage, or without the latter, the muscles easily get strong.

I have said no word of the use of continuous cold so much employed here before the bandage and splint combined were found to triumph readily over most cases. It is still occasionally employed. The method I have elsewhere detailed at length in the "International Lecture Series." It gives us a resource of great value if the less troublesome plan fails; and failure is rare unless the neuritis has gone up the nerve into the sacral plexus, or unless the pain is really spinal in its origin. My former published cases involved ice and splint-rest. Those I have shown you of late were treated chiefly with the tight bandage and long splint, to which you may add ice-bags at need. The rapid gain to be had in an old case of sciatic pain out of these means—the flannel bandage, splint-rest, and ice—must be seen to be fitly appreciated, and I may add that in mild cases the tight bandage used alone is often of value. I do not claim for these simple means any such certainty as seems usually to be demanded from novel methods. I find, however, that I rarely fail, and that my colleagues, like myself, are using these means. It is with me an old treatment, for in 1872, in my book on *Nerve Injuries*, p. 72, I used these words:

"When the disease is really subacute and the nerve tender on pressure for some considerable part of its length, I insist upon the most absolute rest. If it be the leg which is attacked, the patient must go to bed and consent to wear a carved splint for several weeks. If it be the arm a splint answers to put it in a state of repose, and without this it is vain to employ other means.

Cold should be used over the nerve-track by means of Chapman's spine-bag, or better, by such as are now made by the Davidson Rubber Company, which are thinner than those of English make. The caoutchouc bag should be inclosed in a case of thin flannel, and may then be kept *in situ* by a splint and a bandage, if a splint be worn. In most instances I have used them over nearly the whole length of the main nerve, and have usually contented myself with their employment in the daytime. In some cases, however, I have had them renewed twice in the night, and this plan I believe to be the better of the two. The only difficulty lies in the first pain from cold, and is easily overcome. The relief afforded is often remarkable, and the loss of the nerve in size, hardness, and tenderness most gratifying."

The following briefly stated cases, for which I am indebted to Dr. J. M. Taylor, sufficiently illustrate my practice. Many more might have been added:

J.M., thirty-six years of age, born in Ireland, a carpenter, as a boy had some kind of bone-disease, involving the left tibia, with a purulent discharge. Eight years ago he fell forty feet, hurting his left hip. He drank rather freely of whiskey, smokes excessively, and denies venereal disease. There was no neuralgia in the leg until three years since, when it began with a dull pain in the region of the sciatic notch, and passed along the outer aspect of the thigh to the knee. The pain is now confined to the course of the left sciatic nerve; it is constant and worse at night; it is increased in the act of sitting down, and on rising from this position there is much less pain.

Examination of the various organs proved negative. A scar was found on the left leg, at the junction of the upper and middle thirds of the tibia; there is another a little posteriorly to this, and a third a little lower down; these resulted from an old sore, which finally healed ten years ago. The pupils react to accommodation and light; knee-jerks and elbow-jerks, and plantar reflexes, etc., are normal.

The measurements of the thigh, nine inches above patella, were: R., 21 in.; L., 18 in.

The thigh, six inches above the patella, measured: R., 18¼ in.; L., 16 in. The calf: R., 13 in.; L., 13½ in.

He differentiated well as to touch, tested with the æsthesiometer in the distribution of the left sciatic, also on the hands and feet; localization was good; urine analysis was negative.

The patient was admitted to the hospital February 18, 1892, in a state of extreme suffering.

The treatment ordered was absolute rest, good diet, milk between meals, iron and quinine, flannel bandage, and massage. He managed, with phenacetin, to do without opiates, and on the fourth day of treatment he ceased to feel acute pain.

On March 3d no pain was complained of and the splint was removed; the limb was kept straight.

On March 14th the weight cautiously put upon the left leg was followed by no pain on movement or pressure.

On March 30th the man was well able to move freely without pain; no cautery or treatment other than the bandage and splint was carried out, massage having been abandoned early. He had a slight

relapse on the 16th, owing to his having risen incautiously and without a crutch, to assist a patient. This was a clear case of sciatic neuritis, with much wasting.

DOUBLE SCIATICA.

K. P., a porter, fifty-seven years old, a German; married, with seven children; was never ill until December, 1891, when he had what he describes as a bilious attack, which kept him abed three weeks. He broke two ribs three years ago. There was no evidence of syphilis. In October, 1891, he had a rheumatic swelling of the right ankle. A little later the pain extended up the line of the posterior tibial nerve, and generally along that of the main trunk. It was worse upon exertion, and was eased by recumbency. Nevertheless, he went on with his rather heavy work until, after exposure to wet, the pain became far worse and the knee somewhat stiff. At times he could no longer walk, and had also aches in the back and in the left leg.

In August he had severe cramps in both legs, and limped increasingly. Still, under dire pressure of need, he continued to work. Late in August he had solar exhaustion, and at the Pennsylvania Hospital was treated by ice-rubbing. This, he thinks, chilled him severely. The next day intense pain arose in the left leg, grew worse, and he became able to work only intermittently. The pain now (October 14th,) on admission, is very severe over the right sciatic and in the thigh and the calf of the right leg. There is, also, pain on pressure, but none in the sciatic notch or in the popliteal space. In the left leg pain is very marked on pressure along the entire course of the sciatic. There is no pain in the back.

Measurements.—Thigh: R., 18 in.; L., 16 in. Calf: R., 13½ in.; L., 13 in. Dynamometer: R. hand, 125; L. hand, 125.

The knee jerks on both sides are normal, and there is no clonus; the elbow-jerks on both sides are normal, and there is no impairment of muscle-jerks; sensation is everywhere good; the heart, lungs, kidneys, etc., are normal. To stand long occasioned pain in both legs, especially in the thighs; walking is difficult and painful. In November, 1892, on taking charge, I found this man in bed, having had elsewhere many forms of treatment, all unsuccessful. He was ordered full diet, rest in bed, with flannel bandages to both legs. On the third day he became nearly free from pain. Thereafter the usual changes as to splint and bandage were made. It seems needless to repeat them.

On December 2d he was allowed to walk a little on crutches, but not to sit down. Two pain-points in the upper thigh were lightly cauterized. He was discharged December 12, 1892, apparently well. This appears to have been a case of true double sciatica, probably rheumatic. I learn that he is now (April 1st) well and at work. The immediate effects of the splint and bandage were very gratifying.

G. C., sixty-five years of age, is a machinist; he drinks and smokes moderately; is very rarely ill. During the War he had "camp fever." He denies venereal history. He is married, with five children living and four dead. Suddenly, six weeks ago, pain began in the left hip and leg; the left foot feels asleep quite constantly; the pain grows worse at night, on change of weather, on rising from a chair, and while walking or going up steps.

The man is pale and thin and has the gait of one in much pain; the left leg is held stiffly. The left knee-jerk is slightly in excess of the right. Pressure over the left sciatic notch causes pain, and also along the course of the nerve. He was admitted to the hospital March 5, 1892, and was ordered absolute rest in bed, flannel bandages, straight splint, extra diet, milk, iron, and cod-liver oil. On March 10th the report says that the pain disappears in the daytime, but remains at night, sufficiently, at times, to keep him awake. On March 13th all pain has disappeared, except a soreness over the external condyle of the femur and external malleolus where it is in contact with the splint. He now sleeps well. On March 18th all pain is lost, even upon deep pressure. On March 21st the splint is removed in the daytime, but the limb is to be kept in extension and quiet. The splint was applied at night until the 26th inst. The bandage was constantly used, and he walked with crutches. He has had slight relapses, necessitating the use of the splint for a day or two. On March 28, 1893, he was discharged, well—a rapid recovery.

October 14, 1892. P. G., fifty years of age, had sciatica and erythromelalgia. The family history was negative. He was a married man with six children, all well. In the army he had a bad attack of measles followed by dysentery, and later typhoid fever; he was ill five months. After the War he had malarial fever. Seven years after the first attack of dysentery he had a second attack which lasted five years, during which time he passed much blood and mucus; most of this time he continued at work and often voided twelve stools daily. In the last five years the man had been pretty well. He had never had any special injury, but has not been very strong since the last attack of dysentery. He worked as a lumberman for five years, being out in all weathers. In January, 1889, he began to work in the coal mines. Since his army life he has had some fleeting rheumatic pains now and again. The present trouble began January, 1889, while at work in the mine, with severe shooting pain in the right arm and shoulder, noticed while at rest, but disappearing on motion. This lasted three weeks. He sleeps habitually on the right side and had need to keep the arm flexed. One month after this, pain began in the left hip, shooting down the course of the sciatic to the calf and ankle, and being of greatest intensity from the knee to the ankle. He was then confined to bed four weeks; on the slightest movement the pain was much increased; this gradually lessened, but the man was unable to work for five months. He describes the pain, when it began, as a "burning and crawling sensation in the right leg, as if the flesh was on fire"; this continued in both feet in very severe degree; he could place his right foot on the floor, but not the left one, on account of excessive pain. After two months' treatment he had improved, but was unable to work for five

months. He was pretty well until January, 1892, at which time pain of similar kind, but more severe, attacked the back and left hip, seeming to warp the body to the left side. Much pain was caused by any attempt to straighten the body, shooting down the left leg into the foot and toes. He was again confined to bed for four months. He was in the Jefferson Hospital in May, 1892, for five weeks. He finally was well enough to go home, but could not walk, and on arriving the pain grew worse. Since May, while standing with the left leg pendent, the blood seemed to accumulate in the foot and leg up to the knee and cause intense pain.

The left leg is noticeably shrunken and flabby; there is considerable pain on pressure over the sciatic notch, with soreness over the calf muscles; but none in the popliteal space; there is no shortening of the limb. The foot is red and hot.

Measurements.—Thigh: R., 17 in.; L., 15 in. Calf: R., 12½ in.; L., 11 in.

There is slight clonus in the left leg; but none in the right; the knee-jerks on both sides are normal; the plantar and skin reflexes are normal; there is slight hyperæsthesia in the left leg below the knee; the heart, lungs, etc., are normal; the bowels are inclined to be loose and irregular; the appetite is fair; the digestion poor.

This man, while in the standing position, declares himself unable to allow his heel to touch the ground, asserting that it would pain so increasingly and furiously as to "drive him wild." There is also pain on pressure over the entire sole of the foot; pressure also caused an intense flushing of the surface.

The treatment ordered was absolute rest, flannel bandages, the straight splint; massage, except to the left leg; cod-liver oil, malt, extra food, iron, quinine, and strychnine.

On October 26th the pain was so intense that ice was applied. On December 2d, the vasomotor difficulty not lessening satisfactorily, the left leg and foot were elevated. Internally, sodium phosphate was ordered, forty grains, in hot water, an hour before meals, to relieve the constant catarrhal condition of the stomach.

On December 19th the man was very much improved in respect to the sciatic pain; he gained in weight and vigor, and he was allowed to go home on the 20th, as he declined to remain longer. He still wore the flannel bandage and used crutches. The flushing of the foot was not better; the hyperæsthesia of the member was little altered. As usual in my sad experience of erythromelalgia, nothing did much good for the foot, although heat, cold, electricity, and massage were used with care, and I give the case as it left us, because of the great gain in the sciatic pain, which, if not well, was vastly bettered by local rest and the bandage. The long elevation of the leg and foot seemed to make the nerve-tracks more tender, a result which I have seen before and since, nor did it help the vasomotor complications. I presume this man to have a quite distinct case of erythromelalgia, with sciatic and terminal neuritis.

You may with reason ask what I do if the treatment by splint-rest and bandage, or by splint-rest and ice, fail. At first, to clear my experimental therapeutics from needless doubt, I used these means only in cases which I was sure were sciatic neuritis, and this alone. I have elsewhere recorded the results.[1] Of late, and since I felt secure as to my process, I and others have used these means in cases of more dubious nature—in double leg-pain, in those who had certainly troubles in the lower cord. In such examples of sciatic pain of central origin there have been many failures to record—many cases in which splint-rest did no good, or little. In the true sciatic cases which finally defy all medical means, there remains for consideration nerve-stretching. I have seen it fail when my own milder means succeeded. I believe that when surgical nerve-stretching is employed we should at once follow up its use by that of the roller and splint-rest. Some of the relapses which follow its successful use have, I am sure, been due to neglect of the precautions with which in every case of neuritis I desire to surround my patient. In conclusion, I desire to add that I do not look upon splint-rest and the bandage as certain to cure all sciaticas; but as sure to relieve or cure most cases, and as valuable adjuncts to whatever other means becomes desirable.

SUPRA-PUBIC CYSTOTOMY IN TWO STAGES.

BY N. SENN, M.D., PH.D., LL.D.,
PROFESSOR OF THE PRACTICE OF SURGERY AND OF CLINICAL SURGERY, RUSH MEDICAL COLLEGE; PROFESSOR OF SURGERY, CHICAGO POLYCLINIC; ATTENDING SURGEON, PRESBYTERIAN HOSPITAL; SURGEON-IN-CHIEF, ST. JOSEPH'S HOSPITAL, CHICAGO.

SUPRA-PUBIC cystotomy for the removal of stone in the bladder, the operative treatment of intravesical tumors, or the formation of a temporary or permanent fistula in obstructive diseases due to enlarged prostate, has become a legitimate and permanent procedure in surgery. The technique of the operation is destined to undergo improvement. Distention of the bladder and rectum renders the prevesical space more accessible, and Trendelenburg's position is of great value in all supra-pubic intra-vesical operations. If the bladder itself is healthy, the high entrance into the organ for therapeutic purposes can be effected with little or no immediate or remote risk to life. In such cases the ideal after-treatment would be suturing of the vesical and external wounds, thus placing the parts in a condition for healing of the visceral wound by primary intention. Such a result has been obtained only in exceptional cases, even by surgeons of large experience and specially skilled in the performance of the operation.

[1] International Lecture Series.

Attempts have been made to prevent contact of septic urine with the recent wound by resorting to drainage of the ureters after supra-pubic cystotomy. C. Willems[1] advocates this practice, which, he states, is a delicate yet perfectly practicable procedure. In hypogastric lithotomy it is advisable, whenever union of the wound in the bladder is important and subject to prejudicial influences—in fact, whenever the urine is unhealthy and septic. The ureters should also be drained after the removal of a vesical tumor, whether by hypogastric or perineal incision. The wound is thus protected from contact with morbid urine, and antiseptic plugging of the vesical cavity is permitted.

The patient is placed in the Trendelenburg position, the pelvis being raised about fifteen inches from the table. The abdominal viscera no longer press the walls of the bladder in contact, and the trigone can readily be seen through the hypogastric incision. A catheter, with a Y-shaped extremity, is then passed backward through the urethra. The two branches are next introduced into the ureters. The procedure is a delicate one; the upper part of the mucous fold over the orifice of the ureter must be seized with forceps of the kind used for fixing the conjunctiva oculi. Otherwise the very movable vesical mucous membrane may be pushed forward. As the vesical part of the ureter is a narrow funnel, the passage of the catheter needs skilful manipulation. The ureter tolerates the catheter very fairly. In a case of Pawlik's the woman tolerated its presence for forty-eight hours; in Schede's (operation for utero-vaginal fistula), for seven days; and in Albarran's (also a woman), for ten days. The catheter thus allows full time for perfect union of the vesical wound.

This after-treatment is too complicated and difficult for the average surgeon, and in many cases of septic cystitis it is not applicable. Most surgeons have, therefore, discarded primary suturing of the visceral wound and rely on drainage and healing by secondary intention. Healing of the wound usually takes place in from four to eight weeks. Future research and experience will undoubtedly enable us to devise some means by which primary healing of the wound will be the rule and not the exception in such cases, and thus shorten the period of recovery to a minimum. The matter is, however, entirely different when supra-pubic cystotomy is performed in a case in which the bladder is the seat of a septic cystitis, and such cases most frequently require the services of the surgeon. The adipose and loose connective tissue in the prevesical space, which constitutes a considerable part of the supra pubic route into the bladder, is exceedingly susceptible to infection with pathogenic microbes. The urine in such cases is ammoniacal, toxic, and irritating, and, when brought in contact with the prevesical tissues, exceedingly prone to cause necrosis. The pus-microbes contained in decomposed, putrid urine find in the prevesical space the most favorable conditions for the exercise of their specific pathogenic properties. Under such circumstances the wound frequently becomes the seat of sloughing and phlegmonous inflammation, in spite of the most rigid precautions. Suturing of the margins of the vesical wound to the abdominal incision furnishes no protection against this complication. The same can be said of drainage of the bladder and packing of the wound with iodoform-gauze. I have lost two patients from extensive sloughing of the prevesical and paravesical connective tissue. In one case the post-mortem showed that the base of the bladder was nearly separated from the surrounding tissues by extensive necrosis of the adipose and connective tissue interposed between them. It has occurred to me that this source of danger might be successfully avoided by performing the operation in two stages, and I have resorted to this modification in a number of instances, with most gratifying results.

The modification of the operation that I propose is based on the familiar surgical fact that granulating surfaces furnish an almost absolute protection against infection. The first operation is performed under the influence of an anesthetic. The rectum and bladder are distended in the usual manner. The field of operation is rendered aseptic, and the bladder is exposed freely, by dissecting away the prevesical fat over an oval surface about two inches in length and half as wide. After arresting the hemorrhage the wound is firmly packed with iodoform-gauze. The external dressing should be securely fastened by strips of adhesive plaster, which are made to encircle the pelvis and which prevent the dressing from becoming displaced. At the end of five days the dressing and iodoform-gauze are removed, and the bladder is distended and incised without the use of an anesthetic, if it is intended to simply establish a supra-pubic fistula, or if a small stone is to be removed. More serious intra-vesical operations would require the use of an anesthetic. If the wound has remained aseptic it will now be found covered throughout by a layer of active granulations. These granulations have closed the connective-tissue channels, and have shut out from the wound the balance of the prevesical space. If no anesthetic is used the surface of the wound is brushed over with a 5 per cent. solution of cocaine five minutes before the operation. The bladder and rectum are distended in order to render the anterior wall of the bladder more accessible. The bladder is in-

[1] Annales de la Soc. de Médecine, Ghent, 1892.

cised and drained in the usual manner. The septic urine is harmless to the granulations, and thus the dangers of the operation are minimized.

It must be admitted that in patients greatly debilitated by the disease that rendered the operation necessary, the immediate risk of the operation is greatly diminished by performing it in two stages. Another great advantage accruing from this modification of the operation is that at the time the second step is carried out the wound is already in a favorable condition for definite healing. For the purpose of illustrating the value of this modification of performing supra-pubic cystotomy in affections of the bladder complicated by septic cystitis, I will briefly report two cases that have recently come under my observation.

Case I.—A. L., an obese man, aged sixty-eight years, had been suffering for two years with symptoms indicative of the presence of stone in the bladder. Frequent micturition, severe pain after each act, and occasionally slight hematuria, were the most prominent symptoms during the first year. About a year ago cystitis set in, with gradual and progressive aggravation of symptoms. The quantity of pus and mucus in the urine increased, and the patient's general health became greatly impaired. At the time of his admission into the Presbyterian Hospital he was extremely anemic, with rapid and feeble pulse and impaired appetite. The quantity of urine secreted during twenty-four hours varied from thirty to forty ounces; the specific gravity was 1012; the secretion was ammoniacal, and contained large quantities of pus, mucus, and bladder and renal epithelia. The filtered urine was found to contain a considerable amount of albumin. It was evident that the morbid process had extended to the pelves of the kidneys by an ascending inflammation. The prostate was enlarged, and a stone in the bladder was readily detected by the introduction of Thompson's sound.

The patient was suffering excruciating pain, and begged to be relieved by an operation as soon as possible. Salol was given in five-grain doses four times a day, and the bladder was washed out twice a day with a solution of boric acid. A concentrated liquid diet and daily warm baths constituted the remainder of the preparatory treatment. At the end of a week of such treatment, the first part of the operation was performed. Chloroform was used as an anesthetic. After washing out the bladder, ten ounces of boric acid solution were injected, and the same quantity of fluid was used to distend Trendelenburg's rectal bag. The supra-pubic region was thoroughly disinfected, and the bladder exposed in the usual manner. The prevesical fat was dissected away over an oblong vertical space two inches in length and an inch in width at the middle. No ligatures were required. The wound was packed with iodoform-gauze in such a manner that the margins of the external wound were separated at least an inch and a half or two inches. The external dressing was retained in place by strips of adhesive plaster which encircled the pelvis. The bladder was evacuated, and the rectal pouch removed.

The symptoms were not aggravated by the operation, and the patient recovered promptly from the immediate effects. Five days later the dressing and tampon were removed, and the whole wound was found covered by a layer of active granulations. The anterior wall of the bladder presented the same appearance as the remainder of the wound. The wound was freely brushed with a 5 per cent. solution of cocaine. The bladder and rectum were distended as before, and the granulating part of the anterior wall of the bladder was brought within easy reach. Little, if any, pain was experienced by the patient when the bladder was incised. A large phosphatic calculus was found above and behind the prostate. The stone was removed in pieces, as it broke into numerous fragments when it was grasped with the forceps. The interior of the bladder was sacculated, and presented the typical appearances of long-standing cystitis. A large drain was introduced into the bladder, and the space between it and the granulating wound was packed loosely with iodoform-gauze. The whole operation was performed with the greatest facility, and was not productive of much pain. Although the patient died about a week later of uremia, the wound remained in a satisfactory condition. The granulations retained their vigor, in spite of being continually irrigated by the ammoniacal septic urine.

Case II.—The second patient was a young man, twenty-five years of age, born in the South, where he had always lived until recently. He had been operated upon for stone in the bladder in October, 1891. It appears that the rectum was wounded at the time, as a urethro-rectal and a urethro-perineal fistula remained. Evidently, recurrence of stone in the bladder took place within a few months after the operation. For nearly a year he had suffered from intense vesical distress. He was admitted into St. Joseph's Hospital, March 15, 1893. His general health was not much impaired. Urination took place on an average every half-hour. The urine was ammoniacal and heavily loaded with pus and mucus. The perineal fistula communicated with the opening in the rectum and urethra. The stone was detected as soon as the steel sound entered the bladder. Rectal examination revealed a hard mass just above the prostate, which was evidently a large stone in a sacculated part of the bladder. The vesico-rectal septum at this point was exceedingly thin. It was found impossible to pass the sound over and beyond the stone.

The conditions in this case precluded any other operation but supra-pubic cystotomy. The patient was carefully prepared, but owing to the existence of the fistulous opening near the neck of the bladder, it was found impossible to distend the organ in advance of the operation. When the perineal opening was closed with clamp-forceps, the fluid escaped into the rectum. I had, therefore, to cut down upon an empty, contracted bladder. The rectum was distended in the usual manner. The space between the peritoneum and the pubes was limited, rendering the

approach to the bladder difficult. The bladder was contracted, and its walls much thickened. A large, soft phosphatic stone was found in the *bas fond* of the bladder, which had become sacculated, and held the stone firmly in place. The greater part of the stone was removed in fragments with a lithotomy spoon. The mucous membrane at the base of the bladder was incrusted with phosphatic deposits. After thoroughly cleansing the bladder by irrigation, a large drain was introduced into the deepest part of the bladder, and the space between it and the wound was packed with iodoform-gauze. The patient rallied well from the immediate effects of the operation, but in spite of the most careful precautions, extensive sloughing of the margins of the wound and the prevesical tissues occurred, which, for a few days, imperilled his life. After the elimination of the necrotic tissue, healthy granulations made their appearance, and from that time the case progressed favorably.

These two cases speak for themselves. In both instances the stone in the bladder had become the indirect cause of septic cystitis. In the first case the patient was old, extremely anemic, marantic, and was, at the same time, suffering from a fatal renal complication, and yet the wound did not become a source of danger, because the incision in the bladder and the extraction of the stone were postponed until the external wound had become protected by a wall of granulation-tissue. In the second case, the patient was a young, robust man, and yet in spite of the most painstaking precautions, the fresh wound became infected by the septic urine, with extensive sloughing, constituting an imminent source of danger to life.

A study of these cases and the remarks that I have made lead me to formulate the following conclusions for further deliberation :

1. Necrosis and phlegmonous inflammation of the margins of the wound and the tissues in the prevesical space (cavum Retzii) not infrequently occur as complications of supra-pubic cystotomy, if the operation is performed for affections complicated by septic cystitis.

2. Supra-pubic cystotomy in two stages greatly diminishes, if it does not entirely overcome, this source of danger.

3. In the first operation, the bladder is freely exposed in the usual manner, when the prevesical fat is dissected away over a vertical oval space at a point corresponding to the location of the proposed visceral incision, after which the wound is packed with iodoform-gauze, and the external dressing is applied in such a manner that it cannot become displaced.

4. The incision in the bladder and the intravesical operation are postponed until the external wound has become covered with a layer of active granulations, which usually requires from four to six days.

5. The second operation can be performed with the aid of cocaine, without general anesthesia.

6. This modification of supra-pubic cystotomy diminishes the immediate risks of the operation, and affords protection against a number of serious *post operationem* complications.

STOMACH-WASHING IN INFANTS.[1]

BY HENRY E. TULEY, A.B., M.D.,
OF LOUISVILLE, KY.

SINCE the recommendation by Epstein,[2] of Prague, in 1880, of irrigation of the stomach for the treatment of the gastro-intestinal diseases of infancy and childhood, this procedure has been gradually more and more extensively used. It was not, however, until his second report in 1889, at Wiesbaden, before the meeting of the Association of Naturalists and Physicians, that the real value of the measure became recognized. To Dr. A. Seibert,[3] of New York, is due its introduction into this country, who, at a meeting of the Section of Pediatrics of the New York Academy of Medicine, in November, 1888, presented the first report on the subject, comprising a series of cases of acute dyspepsia, and of acute and chronic enteric catarrh, with vomiting, in infants between seven weeks and one and one-half years of age, which were successfully treated by lavage, with and without medication.

Though extensively used for the past four years in New York, comparatively little is known of the measure elsewhere in this country. The object of this paper is to call attention to this valuable therapeutic procedure, to describe the necessary apparatus and its application, and to briefly state the indications for its use, with the report of a few cases.

The apparatus used in stomach-washing consists of a not too flexible soft-rubber catheter, No. 13, American scale, about twelve inches in length. This is attached to a bit of glass tubing, two or three inches long, through which the contents of the tube can be observed in their passage. The glass tube is attached to another rubber tube, and this finally to a glass or hard-rubber funnel, with a capacity of from one to three fluidounces.

Plain lukewarm water, previously boiled, is the only fluid that should be used. Generally not more than one pint is required to wash out the stomach thoroughly.

The child is seated upright in the nurse's lap, its arms being secured under a rubber sheet, with its head resting on the right arm of the nurse, and inclined slightly forward. The child's tongue is depressed with the left forefinger, and the tube is passed back-

[2] Prager medicin. Wochenschr., 1880. No. 45.

[3] Archives of Pediatrics, December, 1888.

ward into the pharynx, advantage being taken of the child's gagging (which will occur from titillation of the pharynx) to pass the tube rapidly into the stomach. In most cases no oil or vaselin is needed; the tube should simply be wet before its introduction.

There is often some gas in the stomach, and if water is poured in the funnel immediately upon the descent of the tube, the fluid may be prevented from flowing into the stomach by the presence of gas in the tube, and not by an obstruction at the eye of the catheter, as one might imagine. A glance at the glass tubing will suffice to show whether the tube is filled or not. This difficulty is obviated by elevating the funnel as high as possible, perhaps for half a minute, to allow the gas to escape. After the stomach has been filled, the funnel is depressed below the level of the viscus, to allow its fluid contents to siphon out, after which one or two funnelfuls of water are again allowed to flow in, to be immediately siphoned out, as before.

There may be lumps of curds which at first are too large to pass through the catheter. These can often be broken up, and dissolved, by again and again passing water in and out until the particles pass readily through the tube; or, if this cannot be accomplished, the child may be made to vomit by the side of the tube by over-distending the stomach with water. In this way masses of leathery curds and thick, tenacious mucus may oftentimes be brought up, which would otherwise have required repeated washings to disintegrate, if, indeed, that could have been accomplished at all.

The stomach of a healthy nursing infant, for the first few months of life, is generally empty two hours after feeding; that of an artificially-fed infant requires, perhaps, a little longer, say two and one-half hours; but in cases of indigestion curds are sometimes washed out four or five, and even eight, hours after feeding, the period of stomach-digestion varying with the character of the milk, the age, and the health of the patient.

Should there be present considerable prostration and urgent thirst, as is often the case in acute processes, one or two ounces of water left in the stomach will afford relief, and the water will frequently not be vomited, as it might be if given by mouth, as has been shown in a series of cases of obstinate vomiting treated by gavage in the New York Infant Asylum during 1892.[1]

The *diet* after stomach-washing and its method of administration are very important. *No food* should be given at all for at least two hours after the washing, and then only the blandest and most easily digested.

If the child is artificially fed, it should be placed on malted milk for twenty-four or thirty-six hours after the irrigation, not more than half an ounce being given at the first feeding. If a nursing infant, and breast-milk is vomited after the stomach is washed, malted milk may be tried for twenty-four hours, in small amounts, and the breast-milk then resumed.

After washing out the stomach, Epstein puts children on albumen-water (made by dissolving in two pints of water the whites of two eggs, first beaten up in water, then filtered) for twenty-four or thirty-six hours, and then allows them gradually to return to the breast.

In the past two years, in the New York Infant Asylum, where the data on which this paper is based were obtained, there have been fully 1500 stomachs washed, and in no case has any evil resulted, or any contra-indication been noted. The procedure is easily carried out, though it may seem like an operation of magnitude to those unfamiliar with its technique.

The following is a *résumé* of the history of forty-five cases of stomach-washing during the mid-summer

[1] Kerley: Archives of Pediatrics, February, 1892.

months of 1891, records of which were carefully kept. The average age was ten and one-half months. Ten were fatal cases of entero-colitis, with high temperature, prostration, etc., and vomiting. Stomach-washing effectually controlled the vomiting in five cases. Of the remaining five cases, in one the autopsy showed extensive ulceration of the stomach at the pyloric extremity; one had suffered from chronic vomiting from birth; and in three both gavage and stomach-washing failed to control the vomiting. In thirty-two cases there was acute dyspepsia. In twelve of this number there were intestinal symptoms; in six of these the temperature was above 100°. In all cases but one, from two to three washings were found necessary to control the vomiting. In the remaining twenty cases, in which the temperature was 100° or below, with the exception of two cases (requiring two washings), only one irrigation was necessary.

Three were cases of chronic vomiting from birth, which was controlled by from one to three washings. In all of the foregoing cases the same precautions as to diet, as already related, were carefully carried out. The following are illustrative cases:

CASE I.—Louisa F., a well-nourished child, fifteen months old, had been fed on Mellin's food, and was gaining in weight. On the afternoon of July 6th she was given bread and Mellin's food, which had been standing uncovered in the hot ward. She soon after vomited quantities of curds, and during the remainder of the afternoon had six thin and yellow movements. At eight o'clock there was quite marked prostration, the face being drawn and anxious, and quite cyanotic, and the temperature being 103°. Nothing could be retained, food causing gagging and retching. The stomach was washed shortly afterward and two ounces of warm water left in the viscus; this was not vomited. Quantities of fine curds were removed by the washing. After a two hours' rest, the child was fed during the remainder of the night on malted milk at intervals of two hours, only one ounce being given at a feeding. There was but one stool during the night and no recurrence of the vomiting. From this time the child went on to perfect recovery.

CASE II.—Joseph L., a robust, breast-fed baby, aged eleven months, had gained rapidly in weight. On July 23d his mother was away from the Asylum on leave all of the day, the child, in her absence, being fed on partially peptonized milk. At 11.30 P.M. the mother returned, and the child greedily emptied in a short while both breasts, which were filled with milk. During the remainder of the night it vomited, five times, curds and sour milk, and had three thin and yellow stools. At nine the next morning the temperature was 100°. Lavage was practised and quantities of sour-smelling curds removed. Two hours later, at its first feeding, one ounce of malted milk was given. During the afternoon the child was nursed as usual, with no recurrence of the vomiting. There were no subsequent symptoms, and the child made a good recovery.

CASE III.—Lulie J., a poorly nourished breast-fed child, seven weeks old, on the evening of July 20th was reported as having vomited part or all of every nursing during the day, the ejected material being curdled and sour. The temperature was 100°, and the child had had two normal stools. The stomach was washed, a few curds and considerable mucus being removed. Nursing was stopped, and after a rest of one and one-half hours malted milk was given and continued until July 22d. During the night of the 22d the child was nursed twice, and vomited after each nursing. The stools were good and the temperature normal. The little patient was again put on malted milk for twenty-four hours after stomach-washing, the nursing being then gradually resumed. The child made a good recovery and had no more vomiting.

The best results in stomach-washing are seen in cases of acute dyspepsia, in the initial stage, with or without diarrhea and with no fever. Rarely is more than one irrigation necessary.

Lavage is indicated in acute gastro-enteric catarrhs, with vomiting and fever. Usually two washings are necessary, rarely more than three or four. The irrigation improves the tone of the stomach and diminishes the number of stools. It is a valuable and effectual means of combating a troublesome symptom in gastro-intestinal diseases, as it mechanically rids the stomach of accumulated milk and curds, which, unless removed, would pass into the intestines and give rise to irritation.

Lavage is of use in cases in which vomiting has been present from birth, or in which there has been continual regurgitation of food, as it removes curds and thick mucus, the presence of which is nearly always associated with disordered digestion. In some cases it may be found necessary to continue the lavage for perhaps two weeks, at first washing once each day, then every other day, and so on as required; but in the majority of cases vomiting is relieved in from one to three washings repeated on successive days. Stomach-washing is by no means a panacea in controlling this oftentimes troublesome symptom, nor does it preclude other treatment. It is far better than emetics (the disadvantage of which has long been recognized in the treatment of indigestion in infants) and, if properly practised, is a simple, effective, and thorough mechanical procedure, and, as far as I have seen in a rather extensive experience with it, is entirely without danger.

In private practice some objections are raised to its use, as to all new measures; but these, I am sure, will not be offered when once the great benefits derived from its application are seen.

111 WEST KENTUCKY STREET.

CLINICAL MEMORANDA.

SARCOMA OF THE RIGHT LUNG DIAGNOSTICATED DURING LIFE BY THE USE OF THE MICROSCOPE; SECONDARY TO SARCOMA OF THE TESTICLE WHICH HAD BEEN REMOVED FOUR YEARS PREVIOUSLY.[1]

BY D. W. PRENTISS, M.D,
OF WASHINGTON, D. C.

W. H. H. was fifty-one years old. His parents had been healthy. His father was killed in a saw-mill. His mother died of pneumonia, aged sixty-three years. There was no history of malignant disease or of tuberculosis in the family. The man's health had been failing for five years.

When a child he injured his testicle, and again later when riding; but this never troubled him. Five years before his last illness the testicle was again hurt, when it became inflamed and the man was confined to bed for some time, suffering great pain. After this he had to exercise great care of the organ. The testicle was removed four years previously to death by Dr. J. Ford Thompson, who pronounced it sarcomatous.

Pulmonary symptoms appeared in August, 1890. The man had had a very profuse hemorrhage from the bowels in January, 1890. He complained of great pain in the right side over the liver. There was slight cough and bloody sputa, though no large hemorrhage from the lungs had occurred. The sputa were frothy, stained with blood, and occasionally mixed with a fibrinous substance.

I first saw the patient March 29, 1891. He had been under the care of a sectarian practitioner, and had been treated for pulmonary tuberculosis for about nine months.

When I saw him he was greatly emaciated; suffering with pain in the right side of the chest; and coughing and expectorating bloody sputa. At first sight he presented all the appearances of tuberculosis. Physical examination, however, showed a condition evidently not due to pulmonary tuberculosis. The left lung appeared normal on auscultation and percussion. The right lung was solid throughout nearly its entire extent. Air could only be heard to enter the lung in two small areas, one near the apex and another low down in front in the lower lobe. At these points at the autopsy were found respectively a little normal lung-tissue and a small cavity resulting from the breaking down of the diseased tissue.

The sputum was sent to Dr. Theobald Smith for examination for tubercle-bacilli, but none were found.

The principal symptoms in the case were the cough and expectoration, great pain in the side from the pleuritic extension of the disease, extreme emaciation and exhaustion. Decubitus was mostly left-sided. As the case progressed bedsores developed over the hips and sacrum, which added greatly to the patient's suffering.

Treatment was symptomatic—excepting that at the first the man was put on a mixed specific treatment of potassium iodid and mercuric chlorid. There was no clinical evidence of specific disease, but upon a suspicion that there might possibly be a syphilitic taint this treatment was tried. It was continued for about three weeks without effect. Other treatment consisted of morphine (to relieve pain), stimulants, and tonics.

The right side of the chest was enlarged and the intercostal spaces obliterated.

Dr. J. Ford Thompson was called in consultation and the side aspirated, to determine if there was liquid in the pleural cavity. None was found, but instead, only blood and a quantity of substance looking like partially organized fibrin was drawn out, evidently from the lung-substance.

This substance was sent to Dr. Theobald Smith for microscopic examination, and reported by him to be composed of masses of sarcoma cells.

Up to this time malignant disease of the lung had not been thought of, but the diagnosis now became clear, especially when inquiry brought out the fact that a sarcomatous testicle had been removed four years before. The patient died of exhaustion, August 21, 1891, one year after the first symptoms of lung-disease developed.

The autopsy was made four and a half hours after death by Dr. Robert E. Edes.

Emaciation was most extreme.

The whole right lung was sarcomatous. There was a pus-cavity at the lower border containing about two ounces of pus. Nearly the whole lung was bound to the chest-wall and to the diaphragm by strong adhesions. The fourth, fifth, sixth, and seventh ribs were eroded posteriorly by pressure. The upper part of the right lung contained several patches of healthy tissue anteriorly, but the remainder of the lung was replaced by sarcomatous tissue, old, hardened blood-clots, and fibrin. The left lung was healthy, except in the upper part of the lower lobe, which was solidified and grayish in appearance. The right kidney was normal; the left kidney congested, otherwise normal. The spleen was small, but normal. The intestines were normal. There was no enlargement of the lymphatic glands of the abdomen. The liver was normal. The gall-bladder was full of bile. The heart was small and flabby.

The accompanying letter gives the results of the microscopic examination:

DR. D. W. PRENTISS.

MY DEAR DOCTOR: Microscopic examination of sections of the supposed sarcomatous testicle and lung proves the growth to be the same in each organ. The sarcoma is of the variety known as lympho-sarcoma. The sections will not take an intense nuclear staining, which is doubtless due to slight post-mortem degeneration. Yours truly,

W. M. GRAY,
Microscopist, Army Medical Museum.

I have been influenced to report this case on account of its comparative rarity, especially in private practice, and also as illustrating the value and importance of the microscope in diagnosis.

As to its rarity, this is the only case I have seen in a private practice of thirty years; although hospital statistics show malignant disease of the lungs not to be uncommon.

When only one lung is affected it is more frequently the right, in the proportion of 2 to 1.

[1] Read before the Association of American Physicians, at Washington, D. C., May 31, 1893.

Walshe records 29 cases of primary malignant disease of the lung, in only 18 cases of which one lung was affected, and of these 18 the right 13 times and the left 5 times. Kohler reports 31 cases, one lung being affected in only 23; the right 15 times; the left 8 times. The condition is more common in men than in women. Hasse reports 22 cases; 17 in men, 5 in women. (*Ziemssen's Cyclopedia*, vol. v, p. 436.)

Osler, however, states that malignant disease of the lung is more common in women.

Malignant disease of the lung is principally to be differentiated from tuberculosis. The possibility of syphilis should not be overlooked.

DIFFERENTIATION FROM TUBERCULOSIS.

TUBERCULOSIS.	MALIGNANT DISEASE.
Begins usually at apex of left lung, and extends to right lung.	Begins usually in middle lobe of right lung.
Sputa muco-purulent, nummular.	Sputa gelatiniform, mixed with pus and blood, "prune-juice."
Cavities.	Intense dulness over whole lung.
	Swelling of lymphatic glands more marked.
Tuberculous diathesis.	Previous history of malignant disease, as in breasts or testicles.
Tubercle-bacilli.	Sarcomatous or carcinomatous cells.

The only other condition that produces the same extent of intense dulness in the lung is a large collection of fluid in the pleural cavity. This is recognized, of course, by aspiration.

As to syphilis of the lung, its extreme rarity alone is almost enough to set it aside.

Tuberculosis of the lung in a syphilitic subject is common enough—in fact, a distinguished syphilographer (Dr. Taylor, of New York) stated recently that the two diseases go hand-in-hand; that syphilis precipitates pulmonary tuberculosis in a predisposed patient. But syphilis of the lung, as a distinct form of disease, does, however, exist, many cases having been reported, and the early symptoms are much like those of malignant disease of the lungs. The diagnosis may be determined by the therapeutic test.

Finally, it is worth noticing that a man could live, as this one did for months, with such an extent of disease within the chest-walls.

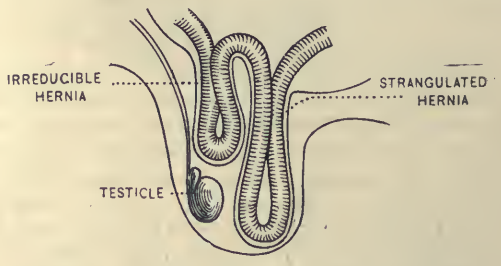
DIRECT AND OBLIQUE INGUINAL HERNIA ON THE SAME SIDE.

BY R. W. STEWART, M.D., M.R.C.S.,
SURGEON TO MERCY HOSPITAL, PITTSBURG, PA.

J. M., thirty-five years old, was admitted to Mercy Hospital, October 23, 1892, suffering from a large scrotal hernia on the left side, which had been strangulated for three days. The patient gave a history of having been ruptured five years ago, and of wearing a truss since that time, until the present hernia descended into the scrotum and became strangulated. The characteristic symptoms of strangulation were present. The material vomited had a fecal odor, the pulse was rapid, and the general appearance of the patient indicated the near approach of collapse, and the urgency of immediate operative interference.

The patient was at once prepared for operation, in which I was assisted by my colleague, Dr. Buchanan, and the house-surgeon, Dr. Stelwagon. The man being anesthetized, and the pubes and scrotum shaved and rendered aseptic, the hernial sac was opened by a longitudinal incision extending from the external ring downward for a distance of five inches, and exposing the hernial contents, consisting of a coil of small intestine, about nine inches in length, which was quite black, but not gangrenous. The constriction, which was at the external ring, being divided, the gut was drawn downward, in order to examine the points of constriction and to assure ourselves of the vitality of the intestine before it was replaced within the abdomen.

At this time it was noticed that there was a peculiar bulging forward of the posterior wall of the sac, caused by a mass the nature of which it was difficult to determine. In order to perform the radical operation for hernia the sac was dissected up to the internal ring, exposing at the bottom of the wound the mass already



Diagrammatic representation of the relative position of the hernias to each other.

referred to. The weight of evidence was in favor of this mass being an old irreducible hernia, and a point was selected where, if it was a hernia, it was thought the sac would not be adherent to its contents. This was carefully incised, exposing within a coil of intestine, the walls of which were so thickened and its surface so altered by firm adhesions to the sac as to be almost unrecognizable. With considerable difficulty the adhesions were broken down. The finger could then be passed with facility between the gut and its sac, and the continuity of the latter with the parietal peritoneum demonstrated. When the gut was liberated from adhesion to its sac it became distended with gas. It was then replaced within the abdominal cavity.

The sacs of both herniæ were tied as high up as possible and cut off, and the common pedicle of both sacs was sutured to the pillars of the ring and the wound closed in the ordinary manner.

The subsequent course of the case was marked only by the development of an orchitis and sloughing of some of the connective-tissue bands that were torn in dissecting up the two hernial sacs.

The chief point of interest in this case is the presence on the same side of two inguinal herniæ, one of which was strangulated and the other not. The explanation given by Dr. Buchanan at the time of the operation seems the most rational one. He thought that the hernia that had been formed five years ago was a direct

inguinal one, that it had never been reduced, though during this period the patient had constantly worn a truss. The gut in the meantime had, however, become firmly adherent to the sac. The strangulated hernia was probably of recent origin, and had descended obliquely through the inguinal canal.

WESTINGHOUSE BUILDING.

POISONING BY OIL OF CEDAR.

BY F. K. BROWN., M.D,
OF PHILADELPHIA.

MRS. P., twenty-three years old, married, having one child and being pregnant three months, took half an ounce of oil of cedar at 10 o'clock P.M. In an hour she was seized with vertigo and a sensation of pins and needles all over the body, immediately followed by a convulsion lasting three minutes and attended with loss of consciousness, rigidity of the body, frothing at the mouth, stertorous breathing, and bilious vomiting.

Ten minutes after the first convulsion there followed another, lasting about ten minutes and attended with the same symptoms as the first, except that the vomited matter was thin and watery at first, afterward resembling coffee-grounds, and finally becoming almost black. There was no diarrhea and no micturition.

When I saw the woman, two hours after she had taken the oil of cedar, she was apparently unconscious, but by vigorous shaking could be aroused. Her face was pale, her expression anxious, and she was somewhat delirious and much afraid that she would die. The skin was cold and clammy; the pulse was rapid and weak, scarcely perceptible at radial artery; the first sound of the heart could be but feebly heard.

Respiration was rapid. There was still a little vomiting of coffee-ground material, and complaint of severe bearing-down pain as though her pelvic organs would be expressed. I at once administered hypodermatically strychnine sulph., grs. $\frac{1}{30}$, and prescribed: ℞. Bismuthi subnitratis, gr. xx; strychninæ sulphatis, gr. $\frac{1}{30}$; morphinæ sulphatis, gr. $\frac{1}{6}$; M. S. Every hour. I also ordered spiritus frumenti, ʒij, every twenty minutes, and hot blankets and hot bottles to be applied to the extremities.

In an hour the patient was much improved. There had been no vomiting for half an hour. The pain was much less and the heart-sounds were much clearer, with a pulse of 90. The respirations were twenty-two per minute. The skin was warm and moist. The prescription of bismuth, strychnine, and morphine was continued every three hours. The whiskey was discontinued. Ten hours later I found the woman out of bed. She maintained that she felt as well as usual. There had been no more vomiting and there was no pain, but she stated that a dark-colored discharge took place from the vagina, which continued until the end of pregnancy. There was suppression of urine for thirty-six hours. The patient did not miscarry, but went to full term, and was delivered of a full-sized but not healthy-looking child.

Arnold Paltauf, Professor of Medical Jurisprudence in the German University of Prague, died May 27th, of malignant disease of the naso-pharynx, at the age of thirty-two years.

PRECOCIOUS PREGNANCY.

BY J. ROBERT BUCHANAN, M.D.,
OF NEVADA, MO.

THE following case is remarkable solely on account of the unusual youth of the subject at the time of parturition.

Mrs. Maggie P., white, of Pike County, Mo., was born September 29, 1864. She was married October 25, 1877, being at the time thirteen years, twenty-six days old. She was delivered on May 30, 1879, at full term, after a normal but somewhat protracted labor, of a healthy, well-developed male child, weighing nine pounds, being then fourteen years, eight months, and one day old. She was a remarkably well-developed young woman, weighing about one hundred and thirty-five pounds. She began menstruating at the age of twelve years. At the time I congratulated myself upon having delivered the youngest woman in my State; nor have I yet met with a physician who has delivered a younger.

MEDICAL PROGRESS.

Periods of Incubation and Infectivity.—A supplement to vol. xxv of the *Transactions of the Clinical Society of London* contains a "Report on Periods of Incubation and Contagiousness in Certain Infectious Diseases" (*British Medical Journal*, No. 1688, p. 958):

Diphtheria.—Eighty-seven cases were considered. In 27, the exposure to infection was for a short period, on a single occasion; in all, with a single exception, in which the facts were doubtful, the period of incubation was seven days or less. In 63 cases the period was four days or less. If to these are added certain other cases, in which the dates at which exposure commenced are positively known, and the sets of cases are taken together, it appears that in 30, or 58 per cent., the period of incubation cannot have been more than four days, while in 45, or 87 per cent., it cannot have been more than seven days. In the large majority of cases infection was attributed to personal intercourse with a sufferer or convalescent. A person may be infected by a patient suffering with diphtheria (*a*) in the incubative stage, (*b*) during the developed attack, (*c*) for a brief period of long, but uncertain and probably varying duration after apparent recovery. In cases of late infection some unhealthy condition of the throat will, as a rule, be found to have persisted, or possibly to have recurred. The evidence further showed that the infective principle of diphtheria can be retained by clothes, carpets, and other fomites for months, perhaps years. It appeared also that infection may take place from cases that seem so mild that the patient never comes under medical treatment, or presents symptoms so little characteristic that their true nature is not recognized even after medical examination.

Enteric Fever.—Seventy cases were considered. In 14 the infection was traceable to a single short exposure to the liability of infection; in 15 other cases the period of incubation must have been less than fourteen days. The conclusion was reached that the interval between

exposure and the development of distinct symptoms is probably most often from twelve to fourteen days; not infrequently it is nine or ten days, occasionally eight, and possibly even less. In rare cases, it is prolonged to fifteen, eighteen, or even to twenty-three days. A case of enteric fever remains infective throughout the whole course of the disease, from the date of the earliest symptoms of the illness until convalescence has been established for at least a fortnight. Evidence is afforded that infection can be conveyed by fomites, and be retained in them probably for at least two months.

Influenza.—The conclusions reached are: (1) that the period of incubation varies from a day, or possibly a few hours less, to four or five days, but the usual period is four or five days; (2) that a patient is capable of conveying infection throughout the whole course of the disease, from the onset of the earliest symptoms, and even after convalescence has been established sufficiently to enable him to resume ordinary occupations a week or ten days at least after the commencement of his illness.

Morbilli.—In 36 cases the exposure to the source of infection was for a short known period, only a few minutes or hours. In 19, or 52 per cent., of these the subsequent interval before the appearance of the rash was exactly fourteen days. In 28, or 78 per cent., the period was thirteen, fourteen, or fifteen days. In three cases only, did the period exceed fifteen days. The evidence afforded by cases in which the period of exposure was not precisely limited confirmed the conclusion that fourteen days is the usual period between the exposure and the occurrence of the rash. Intervals of sixteen, seventeen, and eighteen days probably occur occasionally. In rare cases the interval may be as short as seven days. The duration of the primary, or catarrhal stage, is not constant, and bears no relation to the total duration of the interval between exposure and eruption. It is concluded that the true period of incubation of measles, that is, the interval between exposure and the earliest symptoms, is, in a majority of cases, nine or ten days, but it may be as short as five or even four days, and as long as fourteen. Cases are quoted to show that measles is infectious, not only during the primary stage and throughout the acute attack, but also in some cases after convalescence has been well established, but no period beyond three weeks after the appearance of the rash was met with in which disinfection had been practised. There was evidence that the infection may be retained by fomites for a short time.

Parotiditis.—In 14 cases of single short exposure, the period of incubation was three weeks; a day or two more or a day or two less, in 10. It is occasionally as long as twenty-five days, and more rarely, as short as fourteen days. The likelihood of infection diminishes progressively from the onset of the attack, and will have ceased in two weeks probably, and in three weeks almost certainly. The disease is most highly infectious during the prodromal stage, which is of uncertain duration, and may last as long as four days.

Rubeola (*Rötheln*).—The conclusion is reached that the period of incubation is, as a rule, to which there are many exceptions, more than two and less than three weeks, and that eighteen days is probably the usual period. In a considerable number of cases it is a day or two less than two weeks; in a few it is only eight or nine days; and it is possible that in a small number it may be as short as six or five days. The patient is infective two or three days before the rash appears, and also while the rash is out, but thereafter infectivity diminishes rapidly, and ceases altogether in a week in mild cases, and by the time desquamation is over in the more severe cases. There is little evidence that the infection is long retained by the clothes.

Scarlatina.—One hundred and forty cases were considered. In 34 the exposure to infection was for a short period, measured by minutes, or at most, hours; and in 12 of these the period of incubation cannot have exceeded forty-eight hours. In 19 of these cases (more than half) the period was less than three days, and in no case was the appearance of the eruption delayed beyond the eighth day. It is concluded that the period of incubation is some time between twenty-four and seventy-two hours; it is occasionally less than twenty-four hours, and frequently more than seventy-two hours. Periods of four, five, and six days are often met with, and of seven days occasionally, but it is doubtful if the period is ever extended to eight days. When the infection is conveyed by milk the period seems, as a rule, to be short—two days or less. Infection persists from the onset of symptoms until long after convalescence has been established certainly as long as there is any desquamation; it may still be active eight weeks after the onset of the disease; it is readily preserved and conveyed by fomites.

Surgical and Puerperal Scarlatina.—There is no proof that the period of incubation is longer or shorter in persons that have been injured, or in women recently delivered; but there are grounds for believing that the occurrence of labor or of traumatism may determine the onset of scarlatina in persons that had previously been exposed to infection without taking the disease. The infection of scarlatina may be conveyed by persons that do not themselves suffer—doubtless in their clothes. The symptoms of scarlatina may be very anomalous, or little marked, and, especially in the adult, may consist only of sore-throat; the infection of the disease is particularly likely to be distributed by such cases.

Variola.—The period of incubation is commonly twelve days (from exposure to initial symptoms), but it is not infrequently a day more or a day less. It is only occasionally nine or ten days, and sometimes fourteen or, perhaps, fifteen days. Smallpox is infectious from the onset of the initial symptoms, and until all scabs are cleared off, but it is much more infectious during the height of the active stage of the disease than during the initial illness. The infective principle can be retained and conveyed by fomites, and by the hair of a person that has been in intimate relations with a patient suffering from smallpox.

Varicella.—The period of incubation of varicella appears to be a little longer than that of variola. It is usually fourteen days, but may be a day less or four or five days more. The infection may be derived from a patient at least as soon as the rash appears. A convalescent patient may convey the infection to others. The infection may probably be conveyed in clothes.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 1, 1893.

THE DIAGNOSIS OF CHOLERA.

THE study of the large amount of material afforded by the last epidemic of cholera has cleared up many obscure points concerning the disease. The researches in the field of bacteriology have taken the foremost place, and the methods of investigation have been so vastly improved that, in skilled hands, it is now possible in a doubtful case to make a certain diagnosis of cholera within twenty-four hours.

Perhaps one of the most striking results is to be found in the conclusions that have been arrived at with regard to the possibility of the existence of choleraic infection without clinical symptoms. From what was known of epidemic diseases in general, it had been surmised that during the prevalence of the disease probably very mild cases of cholera occurred frequently and were overlooked, but it remained for bacteriology to demonstrate that such profound differences in the intensity of the infection as were seen in the last epidemic could occur. The fact that in more than one instance virulent cholera-bacilli have been found in the solid feces of apparently healthy men, far from throwing any doubt whatever upon the comma-bacillus as the causative agent in cholera, rather indeed helps to establish its relation to the disease, as these mildest cases of choleraic infection never occur outside of groups of individuals who have been equally exposed, and among whom severe cases of the disease exist; on the other hand, its significance from the point of view of prophylaxis can hardly be overestimated.

ROBERT KOCH,[1] to whom will be generally conceded the best right to speak on this subject, insists upon these points, together with others, and details minutely the methods pursued at the Institute for Infectious Diseases under his care at Berlin in the bacteriologic diagnosis of cholera. It has been found that the original gelatin-plate method is defective (1) because the time required for the making of a certain diagnosis was at least two days, and (2) in that when only a few cholera-bacteria were present they could easily be overgrown by other bacteria and escape observation. The ideal method must, therefore, enable us to make a sure diagnosis in a very short space of time.

KOCH maintains (*first*) that in 50 per cent. of the instances it is possible, simply from microscopic examination of cover-slip preparations, to reach a definite conclusion within a few minutes after the reception of the suspected material. The cholera-bacteria are often present in the small mucus-flakes almost in pure culture, and are then seen in characteristic groups, the single bacilli pointing in the same direction presenting an appearance compared by KOCH to a school of fish in a slowly running stream. In the absence of these clumps, if curved bacilli resembling cholera-bacteria are found associated with no forms except those that resemble the bacilli coli, the diagnosis is still tolerably sure. Nevertheless, in every doubtful case, or to confirm the diagnosis made by microscopic examination, some of the material is (*secondly*) planted in a sterilized 1 per cent. watery solution of sodium chlorid and peptone rendered distinctly alkaline by the addition of sodium carbonate. Since the demonstration by HESSE that the cholera-bacteria require large quantities of oxygen for their development, advantage has been taken of this property in order to separate these organisms from others less strictly aërobic. If a tube of the peptone solution be inoculated with feces containing even a few cholera-bacteria, and be kept in the thermostat at a temperature of 37° C. (98.6°), there will be found after from six to twelve

[1] Ueber den augenblicklichen Stand der bakteriologischen Choleradiagnose. Zeitschr. f. Hygiene u. Infektions-krankheiten, 1893, Bd. xiv, Heft. 2, p. 319.

hours *at the surface of the liquid* an almost, if not a perfectly, pure culture of cholera-bacteria.

The next step (*thirdly*) is the inoculation of a good 10 per cent. gelatin culture-medium, which is poured into plates and kept in the thermostat for from fifteen to twenty hours at a temperature of 22° C. (71.6° F.). If there have been any doubt as to the peptone cultures, gelatin plates are also made from these. *Fourthly*, sterile agar which has been poured into Petri dishes and kept in the thermostat for some days until the fluid which always separates has evaporated, is inoculated and kept for eight hours at a temperature of 37° C. (98.6°F.). *Fifthly*, the cholera-red reaction may be obtained in a culture in peptone solution containing a definite amount of nitrates. The sulphuric acid employed must be free from nitrous acid, and the cultures must be pure. *Sixthly* and finally, injection of pure cultures into the peritoneal cavity will prove fatal to guinea-pigs, in the proportion of 1.5 mgr. ($\frac{1}{48}$ of a grain) of the solid culture on agar (in about 15 minims of bouillon) to 10 or 12 ounces of body-weight.

Curved bacilli other than cholera-bacteria, but morphologically resembling them, occur only with great rarity in the feces of human beings, and, when they do, are easily differentiated by the indol-test and by the animal experiments. In water, however, comma-bacilli are met with very frequently indeed, but can always be distinguished from the genuine cholera-germs by the methods now at our command. In making a study of suspected water 1 per cent. of sodium chlorid and the same amount of peptone are added to 100 c.cm. (about 3 ounces) of the fluid, and the solution placed in a thermostat at a temperature of 37° C. (98.6° F.). At the end of ten, fifteen, or twenty hours agar is inoculated from the peptone culture and poured into plates. The study of the colonies may be then further continued in the manner already outlined.

It will be necessary in future during epidemics, as well as at their beginning and close, to carry on extensive bacteriologic examinations, as it is even more important in cholera than in diphtheria to keep the patients isolated after all symptoms have disappeared until the causative microörganisms are no longer present in the body. We may congratulate ourselves that, in this country, our larger hospitals are more and more asssociating themselves closely with pathologic and bacteriologic laboratories, and that it is becoming generally recognized that not only for the carrying out of research-work, but also for the practical application of the means we already possess for the prevention of the spread of disease, it is essential that the work of the skilled clinician shall be supplemented by that of the bacteriologist.

BOOK REVIEWS.

In his address as President of the American Medical Editors' Association, published as an editorial in the *Journal of the American Medical Association*, Dr. J. C. Culbertson expresses certain opinions on the subject of book reviews in medical journals, from which we must in a measure dissent. Among other things, he says: "I would suggest that book reviews should be limited to the briefest possible acknowledgment of the receipt of a volume. Medical bookmaking is a manufacturing and commercial business, and as such should continuously patronize the advertising pages of our journals. . . . I have no hesitation in saying that the long laudatory book reviews should cease to appear. They strangled the *London Medico-Chirurgical Review* and badly choked the old *Quarterly American Journal of Medical Sciences*."

Apart from the fact that "medical bookmaking" in the proper sense, however much it has been and is abused, is not merely "a manufacturing and commercial business," Dr. Culbertson confounds two distinct things—"laudatory" notices (long or short) of the nature of advertisements of medical books, and genuine reviews. The critical examination of books that assume either to represent the present status of knowledge in any department of medicine and its allied sciences, or to contain new facts or new theories that constitute an advance in knowledge, and the impartial and candid expression of the result of that examination, is one of the highest and most responsible functions of the medical journal. Thus only can error be held in check and due acknowledgment of merit rendered. Honest and truthful reviews by competent writers are of the utmost value to publishers, to authors, and to the profession. Acquainting the latter with the scope of a work and the manner in which the task assumed by the author has been performed, they enable judgment to be formed as to the advisability of purchasing it. By pointing out mistakes of judgment as to arrangement or choice of matter, calling attention to errors of inadvertence in writing or proof-reading, or to graver errors of insufficient knowledge, they

enable the author to make subsequent editions better, and help to keep the reader from being misled. By debating statements open to question, they assist in bringing the truth to light.

The knowledge that their books must stand trial at the bar of critical judgment deters careless and incompetent writers from indulging themselves too freely in the luxury of reckless statement, and the approval of the well-informed reviewer is one of the greatest satisfactions that falls to the lot of the careful and competent author. The reviewer must, of course, be guided only by truth and justice—not by personal favor or dislike, and not by commercial considerations or relations with publishers.

It is the unvarying custom of The Medical News to place books submitted to it in the hands of members of the profession of known fitness for the responsible duty of reviewing, with no other suggestion than an intimation of the space available. This space we try to proportion to the importance of the book; but we are often compelled to lament that the exigencies of a newspaper limit our ability to give good books all the space they deserve, or to take the space required to point out the errors of books more pretentious than worthy.

The best reviews that have ever been written were those in *The American Journal of the Medical Sciences*. It has been well said that from them alone, should the books be lost, the history of medical progress could be reconstructed. Many of the best-informed men in the profession regret that the change of the *American Journal* from quarterly to monthly involved some abridgment in the space devoted to reviews in that journal; though we believe that it can still justly claim a high degree of merit for the character and comprehensiveness of the work of its critical department.

For the commercial puffs, long or short, which our esteemed contemporary miscalls reviews, we have only profound contempt. They are on a par with editorial and other reading notices of pharmaceutic and other manufactures. We shall indeed be glad when these disappear, and the honest judgment of competent critics, expressed briefly as may be, takes their place.

EDITORIAL COMMENTS.

A Standing Committee on Cholera.—The opinion attributed to Surgeon-General Wyman, of the Marine-Hospital Service, that this country has an even chance of escaping cholera this year, and that, if the disease should reach our shores, it is not likely to become epidemic, is shared by most sanitarians. The absence, up to the present time, of any general outbreak in Europe is a favorable circumstance. Clear views as to the etiology and prophylaxis of cholera on the part of medical men and the wide dissemination of this knowledge among the people justify the hope that no general epidemic will ever again occur in the United States. Such immunity, however, can only be obtained at the price of untiring vigilance.

Strict quarantine and local sanitation must be constantly maintained. The experience of last year warrants the expectation that, despite its theoretic shortcomings, our quarantine is adequate to protect our shores at the principal ports of entry under ordinary circumstances of cholera-transportation.

The success with which our local boards of health shall be able to protect us in the event of the disease gaining actual foothold upon the seaboard remains to be seen. It will be measured not so much by the efficiency of the boards themselves as by the coöperation of the profession and, through it, of the citizens of any given municipality.

The best attainable sanitary condition in advance and always and the promptest recognition and management of first cases are essential measures of prophylaxis.

It is scarcely to be hoped that, under existing conditions of want of sanitary organization and scattered population, this country can cope with epidemic diseases, and particularly with cholera, as ably as the British Isles; but we are far from powerless in the matter, and the circular just issued by the Standing Committee on Cholera of the College of Physicians of Philadelphia, inviting the coöperation of the profession in the detection and abatement of unfavorable local conditions, and foreshadowing a closer and more active organization, should cholera actually appear, is a move in the right direction.

The Diagnosis of Dilatation of the Stomach.—The last decade has witnessed a great advance in our knowledge of the diseases of the stomach, and our means of diagnosis in this department have been considerably extended. A better and fuller understanding of the chemism and physiology of this important viscus has laid the foundations for a rational and successful therapeusis. One of the most troublesome of the disorders of the stomach that are not directly mortal is gastrectasis. The diagnosis is simple when the dilatation has reached an advanced degree; but the results of treatment will be in direct ratio to the earliness of the recognition of the condition and the application of appropriate remedial measures. In a recent communication upon this subject, Aufrecht (*Centralbl. f. klin. Medicin*, No. 23, 1893, p. 474) describes two physical phenomena that he has observed in a large proportion of cases of gastrectasis at an early stage, and to which, in conjunction with other symptoms, he attaches considerable diagnostic significance. The first of these consists in a variation in the percussion-note: a gentle blow struck over the stomach in the same situation will at one time be dull, and at another tympanitic. This phenomenon is to be ascribed to the more voluminous and more energetic peristaltic contraction of the hypertrophied wall of the stomach. The

second sign consists in a cracked-pot sound upon percussion over the stomach, which is best elicited at the junction of an area of circumscribed dulness and the adjacent tympanitic area. This is to be explained by the vibration of the volume of air in a portion of the stomach undergoing relaxation secondary to preceding contraction. There seems to be reason to believe that the hypertrophy of the wall of the stomach, upon which both of these phenomena are supposed to depend, precedes for a variable time the occurrence of dilatation.

Medical Legislation in Connecticut.—Connecticut, too, has fallen into the line of medical progress. Its State Legislature has recently passed a bill providing for the appointment by the State Board of Health of three Examining Committees, each to consist of five physicians selected by the Connecticut Medical Society, The Connecticut Homeopathic Medical Society, and the Connecticut Eclectic Medical Association, respectively. Each committee is to frame its own questions and conduct its examinations in writing, and both questions and answers are to be placed on file with the State Board of Health. Applicants for the privilege to practise need but be graduates of medical colleges that are recognized as reputable by any one of the chartered medical societies of the State. The license confers the privilege to treat, operate, prescribe, or practise surgery or midwifery "only in the kind or branch of practice as stated in the certificate of registration." The sectarians are already complaining that the State examinations, even as conducted by three boards, are excluding an undue proportion of their disciples. It would be a mortal blow to make them practise what they preach.

A Peculiar Form of Nasal Obstruction.—Attention has been called to the fact that the current of air through the nares may be obstructed by the approximation of the structures of the alæ nasi with those of the septum narium as a result of deep inspiratory effort. The tendency to this form of closure is increased by the recumbent posture, especially during sleep. When the interference with the aëration of the blood reaches a certain degree the sleeper is aroused, and full inspiration affords temporary relief. This condition may be a source of annoyance, if not of real danger, during the inhalation of ether or chloroform, for purposes of anesthesia. It seems to be dependent upon an enfeebled condition of the dilators and levators of the nose. The introduction of a small body like a shirt-button is sufficient to relieve the obstruction.

A Course of Instruction in Sanitation and Hygiene.—In addition to the activity in professional circles in connection with the institution of measures calculated to prevent the introduction and dissemination of cholera, the American Society for the Extension of University Teaching announces that a course of instruction in sanitation and hygiene has been arranged, to be conducted by Dr. John S. Billings and Dr. A. C. Abbott, Director and First Assistant, respectively, in the Laboratory of Hygiene of the University of Pennsylvania. The course is to open on July 6th and to continue for twelve days at 8.30 A.M.

SELECTION.

"THE CITY OF MAGNIFICENT HOSPITALS."

AN American contemporary proudly asserts that New York might well be called the "City of Magnificent Hospitals." The reason which has led to this outburst of praise is the fact that three new large hospitals are in process of erection in the city, while a fourth is shortly to be commenced. No other city in the New World, we are informed, "can compare in extent with the palatial character and the scientific completeness of its hospital buildings," and "when these various new structures are completed they will form, taken in connection with the other institutions, a magnificent tribute to human philanthropy and medical science." But it is quite possible to have too much of a good thing, even of philanthropy. What have the general practitioners, or, as they are called in the States, "physicians," to say upon this subject? Can they possibly hail with acclamation the foundation of four new hospitals in New York, when the establishment of each institution of the kind must conceivably reduce the number of their private patients? New York may be a "city of magnificent hospitals," but whether the policy has been a sound one which has made it so is entirely another matter. Upon the whole, quite possibly the profession generally would be prepared to dispute the expediency of all this lavish expenditure upon hospitals; both on professional as well as on public grounds, the facilities for charitable relief should be kept within due bounds.—*Medical Press and Circular*, June 7, 1893.

REVIEWS.

INFLUENZA: ITS PATHOLOGY, SYMPTOMS, COMPLICATIONS, AND SEQUELS; ITS ORIGIN AND MODE OF SPREADING, AND ITS DIAGNOSIS, PROGNOSIS, AND TREATMENT. By JULIUS ALTHAUS, M.D., M.R.C.P. Lond.; Senior Physician to the Hospital for Epilepsy and Paralysis, Regent's Park. Second edition, much enlarged. 8vo, pp. 401. London: Longmans, Green & Co., 1892.

MUCH new matter has been added to this admirable study, and it is further enriched with a copious reference-list to the literature of the past three years. It is a contribution to medical history that will have permanent value, and none the less so that it is well indexed. The author elaborates and brings new facts to support his theory that "grippo-toxin" acts as a depressant to the central organic nervous system.

We are glad to note the due prominence given to sanguinolent discharges from the nose among the diagnostic points. Indeed, we have found alarming epistaxis a most troublesome complication in many cases. The richest portion of the book is that dealing with the psychoses, paralyses, and other neural sequelæ of influenza. The section on treatment is unsatisfactory by reason of its fulness. Many authors are quoted, and uncritically, though often their recommendations are worthless. We are disappointed to find not only no clear note of warning against the dangers of antipyretics, but even to see them advised.

We have no doubt that antipyrin was responsible for much of the mortality that figured in death-certificates as heart-failure or influenza. It is true that the author recommends the safeguarding of antipyrin by digitalis—but the better practice is to give neither.

Handbook of Materia Medica, Pharmacy, and Therapeutics. By Samuel O. L. Potter, A M., M.D., M.R.C.P. Lond. Fourth edition, revised. Pp. 781. Philadelphia: P. Blakiston, Son & Co.

The exhaustion within thirteen months of the third edition of Dr. Potter's Handbook, and the demand for a fourth, is in itself sufficient proof of the merited popularity of this work. The features of the book which have done so much to make it a favorite textbook on Therapeutics remain materially unaltered in the present edition. Changes, however, have been made, and the entire text has undergone a thorough revision. The book is essentially one of the accepted materia medica, and only such of the newer remedies as have risen into popular favor because of well-established therapeutic value have been admitted. The omission of such agents as hydrogen dioxid, pyoktanin, the strontium salts, is, however, criticisable. A special and very practical feature is the section on Applied Therapeutics, occupying at least a quarter of the contents of the volume. The book is a thoroughly good one.

Psychopathia Sexualis, with Especial Reference to Contrary Sexual Instinct. A Medico-Legal Study. By Dr. R. von Krafft-Ebing, Professor of Psychiatry and Neurology, University of Vienna. Authorized translation of the seventh, enlarged and revised, German edition. By Charles Gilbert Chaddock, M.D. Philadelphia: The F. A. Davis Company, Publishers.

In its original language this work has long been well known by physicians. One cannot help wondering if its publication in English may not be a somewhat hazardous step, in view of the fact of its possible dissemination among the laity, always sharply on the lookout for facts of the kind. Although these facts are here given with evident scientific motive and manner, it is indeed a large gathering of peculiar morbid, mental, and emotional sexual histories that should be as little known by the unscientific as possible. The translation is well done.

Lessons in Physical Diagnosis. By Alfred L. Loomis, M.D., LL.D. Tenth edition, revised and enlarged. New York: William Wood & Co., 1893.

As a specimen of bad bookmaking it would be hard to excel the publishers' portion of this work. Poor paper, insufficient margins, and execrable illustrations detract from the pleasure with which one should read or study Dr. Loomis's admirable exposition of his subject. A tenth edition has passed beyond the domain of criticism. It is only to be said that the gifted author has brought his book fully abreast of the advanced knowledge of the day, without forgetting the teachings of the past. It is a book well worth the having, giving briefly, but without important omission, the principles and practice of the various methods of clinical examination by the unaided senses or with instruments of precision, and elucidating the diagnostic and pathologic significance of the information so obtained.

The Johns Hopkins Hospital Reports. Report in Pathology, III. Vol. iii, 1893, Nos. 4, 5, 6.

This report contains five interesting contributions. Simon Flexner records two cases of multiple lymphosarcoma, in the lesions of which he found round, oval, or slightly irregularly-shaped bodies, which he thinks may be sporozoa, and of etiologic significance. Henry J. Berkeley contributes a most interesting and elaborate histologic study of the cortex of the cerebellum of the dog; W. T. Councilman reports a case of chronic nephritis in a cow, with the results of a histologic study; H. L. Russell considers the relation of bacteria to vegetable tissue; William T. Howard presents an analysis of 105 cases of hypertrophy of the heart from the autopsy records of the Johns Hopkins Hospital. Taken altogether, the report is a most creditable and valuable one.

Elementary Physiology for Students. By Alfred T. Schofield, M.D., M.R.C.S. 12mo, pp. xii, 372. Philadelphia: Lea Brothers & Co., 1892.

This little volume is neither more nor less than its title implies. It would be difficult to believe that it is intended for medical students, although it will find a useful place among the text-books employed in high schools and normal schools. It is most skilfully put together, and a vast deal of ground is covered without cumbersome verbiage or unnecessary discussion. The language is clear and perspicuous. The arrangement is natural and consecutive. The typography is excellent. The illustrations are numerous and well executed. The book deserves to become popular.

Transactions of the American Pediatric Society, Fourth Session, Held at Boston, Mass., May 2, 3, and 4, 1892. Edited by William Perry Watson, A.M., M.D., Recorder. Volume IV. Pp. 276. Bailey & Fairchild, 1893.

This book does not now call for extended review, as Dr. Osler's presidential address, with its caution against a too narrow specialism, has been published in The News, and most of the admirable papers have, during the year, been abstracted or commented upon in this journal or elsewhere. As a whole, the volume is creditable, and the papers on diphtheria especially are of permanent value.

Transactions of the John Guitéras Medical Society of Undergraduates, University of Pennsylvania, 1892–1893. Philadelphia: University of Pennsylvania Press, 1893.

This little brochure contains an address by the patron of the society, and a dozen communications of interest by members of the society and professors, and other instructors in the University of Pennsylvania, and reflects much credit on all concerned.

SPECIAL ARTICLE.

THE STATE OF PREPARATION OF NEW ORLEANS AGAINST AN INVASION OF CHOLERA.

BY F. W. PARHAM, M.D.,
OF NEW ORLEANS, LA.

THE state of preparation of New Orleans against an invasion of cholera may be considered under two heads:

A. Quarantine arrangements against the introduction of the disease.

B. The sanitary safeguards in the city itself.

A. The quarantine establishment of New Orleans consists of the following stations:

1. That at Port Eads, at the head of South Pass.

2. The Lazaretto, in Pass à l'Outre, an unused pass, out of the way of all incoming ships.

3. The Mississippi River Quarantine-station, situated about ninety miles from New Orleans.

4. The Rigolets Quarantine-station, on the strait between Lakes Borgne and Pontchartrain.

5. The Atchafalaya Quarantine-station, near Morgan City.

The fourth controls all approach through Mississippi Sound and Lake Borgne into Lake Pontchartrain, and the fifth keeps guard over all vessels from the Gulf up through the Atchafalaya. Comparatively speaking, these latter stations may be regarded as unimportant, as our great danger of cholera importation *by sea* lies in the Mississippi River. Our reference, in this paper, will therefore be to the quarantine-establishments in the river, as carried on at the three stations enumerated. We shall discuss these in the order named.

1. Port Eads. No vessel from any quarantinable port is allowed to come into the river during the night. All such vessels are boarded in daylight by the Medical Inspector of the State Board of Health of Louisiana. If this officer finds no reason to suspect a ship, she is given free pratique and comes on up to the city. If cases of infectious disease are found on board, the ship is sent at once to the Lazaretto, to be there treated according to the regulations at that station.

2. The Lazaretto. This is the infectious-disease station. It is situated some distance away from the course of vessels, and about five miles from the main station, to be next described. All vessels with cholera on board would be sent directly to the Lazaretto station from Port Eads. The sick would then be removed to the hospital and the well located at a safe distance. Ample provision will be made here for all contingencies that may arise in connection with the hospital treatment of the sick or the accommodation of the well. Considering the facts that the fastest ships require not less than two weeks for the trip from European ports to New Orleans, and, further, that few immigrant ships come to this city, we can believe that the Lazaretto would rarely become crowded with persons from infected ships. When all, sick and well, had been removed from the ship, she would then be disinfected from the tug, which would go down for that purpose from the Mississippi River Quarantine-station. The sick having all recovered, the passengers would be taken on board and she would proceed to the station now to be described.

3. The Mississippi River Quarantine-station. At this station, about ninety miles from the city, the final, and a most efficient, disinfection is administered to infected ships. Steam, sulphur dioxid under pressure, and mercuric chlorid solutions are the disinfecting measures employed. Four ships can easily be attended to in one day. The provisions for steam disinfection of textile fabrics are especially effective. The disinfection, as practised here, seems, to all who have personally investigated it, the most satisfactory in operation at any port on this continent.

I say nothing of railroad quarantine, because I believe little can be done in this way, for obvious reasons, when cholera shall once have gained entrance into one of our cities. Strict surveillance of all incoming trains, both passenger and freight, is contemplated when the disease has once come into some other port, but no special preparation is at present making to that end, although facilities are ample for providing, on short notice, adequate inspection.

B. The sanitary safeguards in New Orleans.

It must at the outset be confessed that sanitation is at its lowest ebb in New Orleans. The unpaved and dirty condition of many of our streets, the choked-up condition of many of our gutters, the miserable garbage service, the antiquated and deplorably unsanitary privy-vaults and cesspools, some of them having overflow-pipes into our street gutters, and the general disregard of sanitary precautions until some threatening danger rouses our community from its lethargic condition—all these considerations make the sanitarian heart-sick in the face of an impending invasion. If our people could really be brought to believe, with Goethe, that "In peace, patriotism really consists only in this, that every one sweeps before his own door, minds his own business, also learns his own lesson, that it may be well with him in his own house," then cholera-epidemics would lose for us half their terrors.

Last September, under the stimulus of a few suspected cholera-cases in New York, our people, through the exchanges, urged on by the Board of Health, did make a spasmodic effort to get our streets into a cleanly condition. Many of our gutters were unchoked and streets were cleaned, garbage was more promptly removed, and the people generally were brought to a realization of our sanitary necessities. They were made to believe that cholera revelled in filth and that cleanliness was its abomination. With a long pull, a strong pull, and a pull altogether, *something* was done. New Orleans got into her best plight—for a time. The cholera did not come, and our work seemed to have been in vain. At least, having kept the cholera out, nothing more was needed. Our city quickly relapsed into its former condition, and not only that; for, taking its example of the pendulum, having swung so far in one direction, it has now gone to the extreme in the other. It can be truly said that our city never was a more shining mark for cholera than at present. It is true that under the urging of the Board of Health something seems at last to be contemplated for the improvement of our garbage service; that the New Orleans Sewerage Company, under the able presidency of Dr. Joseph Holt, has matured, with the assistance of the best engineering talent of this country, its plans for an admirable system of sewerage, which

will do away with our death-dealing vaults; but these changes can only be effected with time, and our consideration must be of the present.

The city is under control of a political organization, which is not patriotic but self-loving, and little can be expected of it beyond what the public will demand in time of imminent danger. That cholera will gain entrance into this country through New Orleans, our efficient quarantine in the river negatives, so that we must await its coming most probably through New York, or some other port in closer touch with Europe. When it shall have once more pressed its way in, then will our people awake again from their careless sleep and our city will a second time be cleaned, our garbage service will be made more efficient, our privy-vaults will be emptied, and disinfectants will be freely used about drains and yards.

A source of greater satisfaction is our water-supply, wherein we will yield to no superior. Our water is derived from the following sources:

1. The deep or artesian wells. A very careful analysis of these waters has been made by Prof. A. L. Metz, Chemist of the Louisiana State Board of Health. These analyses, all made in duplicate and once or twice in triplicate, show these waters to contain "albuminoidal material that has partly undergone decomposition, and the results of analyses for free ammonia are high, and the presence of nitrites and phosphates indicate sewage-contamination." We can, with Prof. Metz, declare "the deep well-water of the City of New Orleans unfit for domestic purposes."

2. Drove well-water is likewise to be condemned.

The only waters that deserve our consideration are, then:

3. Rain-water, and

4. Mississippi River water.

Rain-water. This is caught from the roofs of houses and stored in cypress (overground) cisterns. Rain-water may be contaminated from several sources: 1. Location in proximity to privy-vaults. Analysis shows this to be a positive source of contamination. This can only be entirely corrected by the adoption of sewerage, although it can be rendered less dangerous by removing the cistern further off from the privy. 2. The washings of the atmosphere and dirt from roofs. This dirt consists of soot, ammoniacal salts, inorganic and organic material from birds, dead insects, decayed leaves, and the like. Accepting the maximum limit of safety of Dr. Smart as 0.020 parts of albuminoidal ammonia per 100,000, much of our cistern water, according to the analysis in 1891, of Prof. Metz, must be regarded as distinctly unwholesome, some showing as much as 0.080, 0.090, and 0.093 per 100,000. If, however, cisterns are cleaned semi-annually and some one of the numerous cut-offs recommended be used, so as to turn off the first washings of the roof from the cistern, this organic matter would be materially diminished. The danger would be still further lessened by the providing of covers for cisterns. We have city ordinances making such covers obligatory, but we have no ordinance requiring the cleaning of cisterns. While much of our cistern water may be considered unsafe for use, still, as a whole, with the indicated precautions taken, it will compare favorably with the water-supply of other cities. During an epidemic of cholera, moreover, we might regard such water as far less likely to become contaminated than many of the comparatively limited sources of supply of some of our larger cities; for drainage, at least, would not be a source of danger to our *cisterns*.

River water. From the careful analysis made by Mr. Metz, this source of supply must be pronounced far the safest for us in a time of cholera-prevalence, no sample of filtered water showing a quantity of albuminoidal ammonia anywhere near the danger-limit; and this must, as our analyst says, be considered "the purest water attainable in this section under existing circumstances." The water has of late been much improved by the introduction of a filter at the works, which now furnish a fairly (although not uniformly) clear water to the people of the city. The misfortune is that the high water-rates have prevented many from taking advantage of this purest source of supply, and these must perforce fall back upon their overground cistern. With attention to the precautions suggested, we can, however, expect no insurmountable difficulty in dealing, during an epidemic, with the problem of drinking-water contamination.

The milk question might properly merit some consideration here, prone as milk admittedly is to become contaminated with infectious poison, and being of such general necessity. Our milk is delivered, first-hand, from carts directly from dairies to their customers. The Board of Health has made a strong effort to secure a pure milk-supply. In this we have been gratifyingly successful. Only recently the courts have conceded the authority of the Board of Health, under city ordinances, to regulate this matter for the good of the community, and numerous convictions have taught such a salutary lesson that we believe we shall, in the future, have far less trouble in compelling dairymen to furnish unadulterated milk. Starting with a pure article of milk, the precautions to be taken, as to boiling, etc., will insure its safety in time of cholera-epidemic.

A consideration of the foregoing facts would lead one to say that New Orleans is well prepared to prevent the entrance of cholera, but that she is not in such a sanitary condition as would make it easy to cope with the disease after it had once gained a foothold here. Watchful vigilance and an energetic handling of the first cases on the part of our very efficient Board of Health might save us, but the fight with us would be against great odds.

427 PRYTANIA STREET.

CORRESPONDENCE.

COMPLICATIONS OF TONSILLOTOMY.

To the Editor of THE MEDICAL NEWS,

DEAR SIR: Desiring to present an article on the subject of "Complications of Tonsillotomy" at the next annual meeting of the Louisiana State Medical Society, I respectfully solicit answers to the following questions:

1. Number of cases of hypertrophy of faucial tonsils operated upon; 2. Complications occurring during these operations, stating nature of complications and number of cases affected; 3. Method of operating in the cases in which these complications developed. In publishing

these cases, I shall, if desired, omit the name of the physician who reported them.

I shall mail a reprint of the article to those physicians who send me a report of their cases.

Very respectfully,

W. SCHEPPEGRELL, M.D.

EYE, EAR, NOSE, AND THROAT HOSPITAL, NEW ORLEANS, LA

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-fourth Annual Meeting, held at Milwaukee, Wis., June 6, 7, 8, and 9, 1893.

(Continued from page 702.)

SECTION ON NEUROLOGY AND MEDICAL JURISPRUDENCE.

FIRST DAY—JUNE 6TH.

THE Chairman, DR. C. K. MILLS, of Philadelphia, delivered an address entitled "The Influence of Special Societies and Section Work on the Development of Neurology in America." He suggested the advisability of limiting the time for discussion to five minutes, except in the case of the reader of the paper, who should close the discussion. He referred to the excellent work done by the Philadelphia Neurological Society, citing this as an example of the advantage of such societies. The American Medical Association can best advance by allotting special work to the sections. The appointment of committees to do special work has been of great value. Too many isolated cases are, however, reported, and papers have not always been well prepared. A great advantage of small societies is that they secure definiteness of aims.

DR. HENRY H. DONALDSON, of Chicago, read a paper on "The Weight of the Brain." In a large number of examinations it has been shown that the weight of the brain is greater in the male than in the female; that it is not unusual in insanity except in cases of wasting disease; and that the brain wastes slightly in old age. These observations, however, are taken from the unfortunate classes. It has also been shown that the brain increases rapidly in size from birth up to seven or eight years, and thereafter more slowly up to fifteen or twenty. Then for the next few years there usually occurs a slight falling off in weight, which, in turn, gives place to an increase up to thirty-five or forty, the weight remaining constant for ten or fifteen years, and then decreasing. These data are obtained from an examination of dead, and not of living subjects; so that the curve representing the course of brain-growth cannot be taken as indicative of the growth of the individual brain. A study of the favored classes might yield different results. Brain-growth is especially rapid during the first year. Cells and their prolongations are the structural elements of the nervous system. All nerve-cells are formed before birth, and the brain increases after birth by the enlargement of the elements already present, and not by the formation of new elements. The granules in the cortex and other localities are undeveloped nerve-cells, which, by growth, are transformed into the characteristic ganglion-cells. The conditions of growth must be delicate; as two individuals, starting with nerve-cells of the same weight at birth, arrive at maturity with very different brain-weight. The size and number of the elements and relative abundance of the medullary substance must be the next step in the interpretation. Race, age, sex, stature, bodily weight, mental condition, individual development, and cause of death are all factors to be considered.

DR. C. H. HUGHES, of St. Louis, read a paper entitled "Dyspepsia as a Nervous Disease, or Indigestion in Its Nervous Aspect and Relations." He pointed out that dyspepsia, as it is generally encountered, is more frequently a secondary than a primary disease; secondary to degenerative or exhaustive changes in the central nervous system. It is a well-known fact that the lowest animals do not have dyspepsia; that the elements of dyspepsia are first observed in trained animals, in consequence of habits of life and environment that bring about the neurotrophic condition from which dyspepsia arises as a secondary manifestation.

DR. J. MADISON TAYLOR, of Philadelphia, read a paper entitled "Abstract of Notes on the Treatment of Exophthalmic Goiter." He reviewed the relationship of exophthalmic goiter to other vascular disturbances associated with enlargement of the thyroid, as myxedema, cretinism, and akromegalia. Current knowledge of the physiology of the thyroid gland does not warrant the hope that much is to be expected from the use of preparations of the gland in the treatment of exophthalmic goiter. A number of cases long under observation were analyzed, and the following summary of treatment was presented:

Regulated rest, with carefully graduated activity, as time and circumstances warrant; systematic measures directed to the upbuilding of the general health; careful attention to nutrition, recognizing the trophic element in the disorder.

Careful attention to the vascular condition, which is most noticeably at fault and which demands the most constant treatment. This includes various measures regulating vasomotor activity, as well as loss of nervous force through the easily disturbed nervous balance. The skin is to be acted upon from the surface by means of certain remedies that seem to exert a control over the constant tendency to vasomotor neuroses, both superficial and deep.

The searching out and remedying of constitutional defects; the elimination of accidental poisons, either diathetic or temporary, or of toxins from whatever cause.

The regulation of the nervous or emotional balance, by careful attention to the habits and environment of the individual; carefully regulating, so far as is possible, emotional strains; making much of moral teachings with those whose will-power and mental equilibrium are gravely at fault constitutionally and as the result of months or years of suffering and susceptibility.

A careful consideration of such measures as are regarded as specifics, as electricity.

DR. DANIEL R. BROWER, of Chicago, read a paper entitled "Suggestions on the Treatment of Locomotor Ataxia." He said that some cases of posterior spinal sclerosis may be cured and some may have the rate of progression considerably impeded. If the disease is recognized in the pre-ataxic stage, rest for three months should be the foundation of the treatment. Potassium

iodid and fluid extract of ergot in full doses, and galvanism are of value. Hypodermatic injections of morphine are valuable to relieve paroxysms of pain. The digestive organs should be carefully guarded, and alcoholic stimulants and sexual intercourse prohibited. In the second stage or the stage of incoördination, when the disease usually progresses rapidly, ergot will sometimes prevent the progression. Suspension is of service, continued as long as possible, from five to fifteen minutes. In this stage the injection of chlorid of gold and sodium is advisable, at the same time employing zinc phosphid and sodium arseniate, as well as galvanism; no benefit may be expected from the internal administration of any preparation of silver. Cold bathing is of value; hot baths are contra-indicated. The pains of the second stage are met by morphine; sometimes phenacetin, antipyrin, or the like answers the purpose better. Patients can be taught to regain some degree of coördination by the practice of standing with the feet close together and the eyes closed. If the patient stands in the bath-tub and has cold water poured on his spine, coördinating control will be more speedily regained. The bladder will need attention to avoid cystitis. Hypodermatic injections of morphine may be used for the relief of gastric crises. In the third stage tonics are indicated; galvanism to the spine and faradism to the surface; injections of cerebrin and other animal products have thus far not yielded favorable results.

DR. T. D. CROTHERS, of Hartford, recommended Turkish baths in treatment, and said sometimes an apparent cure is thus effected.

DR. C. H. HUGHES, of St. Louis, suggested that in cases of apparent recovery the correct diagnosis should have been multiple neuritis.

DR. L. HARRISON METTLER, of Chicago, read a paper entitled "Hemiparaplegia; Report of a Case Completely Recovered after One Year's Duration."

The conclusion was reached that hemiparaplegia may result from a lesion in the lower part of the cord, anesthesia and paralysis appearing upon the same side of the body.

DR. METTLER also read a paper on "Aural Vertigo—Ménière's Disease." He said that medical literature abounds in cases wherein a sudden attack of vertigo, associated with loss of hearing, was diagnosticated as hemorrhage into the labyrinth, without further investigation into the corectness of the inference; but vertigo as a mental phenomenon seems to be of far too complicated a character to presuppose so simple an origin. If the views of Spitzka and Starr are correct in regard to the sensory paths in the medulla, they bear strongly in favor of the sensori-motor theory of vertigo. Every indication points to the fact that the center of equilibration must be looked for, not in one particular part of the brain, but in the harmonious action of the various sensory and motor centers one upon the other. Ménière himself seems to have believed that only the semicircular canals are affected in true Ménière's disease. He, however, ascribed cerebral symptoms to a lesion of the canals on the strength of a single observation, and even that observation was not conclusive as to that particular case. Much confusion has arisen in regard to aural vertigo. Disease of any part of the internal ear, and even of the middle ear, has been termed Ménière's, though Ménière himself restricts the designation to disease of the semicircular canals. Gowers strongly supports the labyrinthine origin of vertigo, but his proofs are inadequate. Though the implication of the semicircular canals in aural vertigo be admitted, it still remains a difficult matter to explain upon his hypothesis the vertiginous symptoms and loss of hearing in all cases. The semicircular canals in the shark have been removed without causing any disturbance of movement. There is no regular correspondence between the degree of deafness and the intensity of the vertigo with total loss of hearing in Ménière's disease. All known methods of diagnosis prove that the nerve itself and not merely the internal ear is affected. Physiologic experiment shows that simple pressure does not cause total loss of hearing, when no injury is done to the cochlea, and no case has ever been reported in which the cochlea was primarily affected, with consequent involvement of the canals and vertigo. Hence it is concluded that in Ménière's disease the lesion must concern the whole labyrinth or lie entirely outside of it. There is little doubt about the central nature of the disease in many of its aspects. The sense of irritation may sometimes be in the semicircular canals, just as sometimes it may be in the eye or in the stomach, but the immediate cause of the vertigo cannot be there, and in view of the few physiologic and pathologic data at hand, there is no justification in assigning all cases of vertigo to an unknown and undemonstrable lesion of the internal ear.

DR. WILLIAM FULLER, of Grand Rapids, Mich., read a paper entitled "A Method of Localizing Points in the Hemispherical Ganglia." He presented a model of the brain made by hardening with great care, separating the lateral halves and slicing each half into segments, three-sixteenths of an inch thick, perpendicular to the long axis of the brain.

DR. FULLER also presented a communication entitled "An Examination into the Question of Priority in Craniectomy for Idiocy." He stated that in 1887 he performed craniectomy for the relief of idiocy, an account of which was published in the *Canadian Medical and Surgical Journal*, in 1887. The operation was ridiculed in both America and Europe at the time, but has since been claimed as originating with European surgeons.

SECOND DAY—JUNE 7TH.

DR. THEODORE DILLER and DR. J. J. BUCHANAN, of Pittsburg, Pa., presented a paper entitled "A Case of Subcortical Cyst of the Lower Part of the Ascending Parietal Convolution; Operation; Recovery." Nearly all of the important symptoms of intra-cranial growth were present: Headache, vomiting, vertigo, convulsions, and paresis. From the history of the case it was evident that a lesion was located in the left Rolandic region, involving principally the hand-center. The absence of sensory symptoms seemed to indicate that the lesion was situated anteriorly to the Rolandic fissure, and from the fact that paresis preceded convulsions, the lesion seemed probably a subcortical one. The relative method of Thane was employed to locate the fissure. A thin sheet of aluminum was employed, cut in the form of a segment of a circle, having an angle of 67° and a radius of three and three-eighths inches, and moulded to fit the average skull, when its straight sides

are applied respectively to the median line and to the part of the scalp corresponding to the fissure of Rolando. While the result of the operation fell considerably short of an entire cure and was, in a measure, disappointing, yet it was followed by distinct and unmistakable benefit to the patient. It is too early to tell what the ultimate result will be. The case offered strong evidence in support of the view that the ascending frontal convolution is exclusively related to motor functions. The cortical representations of the forearm and hand are located in the ascending frontal convolution; the cortical subdivisions of the arm-area are related to each other as follows in the ascending convolution: that for the shoulder is highest, with the elbow, wrist, fingers, below in the order named; the center for the thumb is located in the ascending parietal convolution, a little below that for the fingers. The case confirms the theory that a subcortical lesion is likely to produce paresis before convulsions, and exemplifies the general principles of localization as enunciated by Horsley, Sequin, Mills, and others.

DR. C. B. BURR, of Pontiac, Mich., read a paper on "Surgery in the Insane." He presented a collection of cases illustrating phases of surgery that come under the eye of the hospital alienist, including gynecologic operations; also two cases of melancholia, in each of which trephining had been performed, without relief. Cases illustrating the curative effect of operations, *per se*, are well known to alienists and which surgeons are of late beginning to recognize. Hernia and perityphlitis are relatively common in the insane, but often escape notice.

DR. H. N. MOYER held that the element of consent is extremely important, especially when surgery of a radical character is practised, as, for instance, the removal of tubes and ovaries when there is no apparent local disease, for the effect upon the general nervous system. He said that shock is comparatively slight in operations upon insane persons, notwithstanding their general low nutrition.

DR. JAMES G. KIERNAN pointed out that the position of a superintendent of an insane asylum is a *quasi* legal one. He is the guardian of the patient, and under such circumstances has the right to give consent for the patient for an operation. Especially is this true in case of emergency. The removal of healthy tubes and ovaries is not likely to be followed by permanent improvement. The counter-irritation may produce a temporary improvement, but such operations are not justifiable.

DR. G. F. LYDSTON, of Chicago, Ill., read a paper on the "Therapeutic Use of Static Electricity." He contended that the use of static electricity in medicine has been too closely restricted to the more advanced neurologists. He has found it a valuable agent, especially in the treatment of neurasthenia, particulary in the forms associated with brain-fatigue and sexual hypochondriasis. The application of the static current to the spine has seemed to have a marked stimulating effect upon the genito-spinal center. In no case have any injurious effects been observed, but in some sensitive and neurotic patients the current should be used with a certain degree of circumspection.

DR. L. C. GRAY, of New York, said that too much had been expected in the first place from the use of static electricity. The results had consequently proved disappointing. There was a revulsion of feeling against the agent and it had been largely discontinued, but it seems to be coming into use again. The improved machines of the present day are a great advantage; the results have been surprising in certain cases; especially has it proven useful in cases of muscular atrophy.

DR. DANIEL R. BROWER, of Chicago, called attention to the usefulness of the static current in cases of chorea, and described his method of application, which consists in placing the patient on an insulated stool and applying the current for from ten to fifteen minutes.

DR. HAROLD N. MOYER, of Chicago, presented a paper on "Sodium Arseniate in the Neuroses." He said that arsenic holds a prominent place in the treatment of nervous disorders. The objection to the use of Fowler's solution of potassium arsenite hypodermatically is that it is exceedingly irritating. Arsenic injected beneath the skin has a far less toxic effect than when administered by the mouth. Potassium arseniate possesses the advantage of giving rise to no local irritation, so that much larger doses can be employed. Dr. Moyer has given at a single dose a quantity of sodium arseniate equivalent to from forty to sixty minims of Fowler's solution. It is a common practice to give the equivalent of thirty minims of Fowler's solution as the initial injection. In order to prepare accurate solutions for hypodermatic use, it is necessary to subject the salt to a temperature of about 300°, which drives off the water of crystallization.

DR. M. V. BALL, of Philadelphia, read a paper on "Insanity Among Convicts." He said that when communities recognize that "every society deserves the criminals it has," they will endeavor to correct the evils that in large part cause crime, and will treat malefactors not with a spirit of vengeance, not with a visitation of justice, not as sinners, but merely as obstructionists whom society must place under restraint or remove to a place where they can be of service instead of hindrance; then only will the penal question reach solution. Present modes of justice are puerile. What would be thought of the suggestion that a chronic maniac should be sent to an insane asylum for a year and then be released unconditionally; then, after he had killed someone, that he should again be sentenced for a definite term of one or more years? The danger to society alone should be considered, and the professional criminal placed in durance vile until cured (if that result is possible), or permanently if incurable, and wholly as a protection to society and irrespective of his sanity or insanity, his moral responsibility or irresponsibility.

DR. LANDON CARTER GRAY, of New York, read a paper entitled "What Should Constitute Responsibility in the Medical Sense, in Insanity?" He pointed out that great injustice is likely to be done to the insane by basing the view of their insanity upon the proposition that if a man is able to understand the nature, quality, and consequences of an act, he is legally responsible for such an act. The question of legal responsibility should be determined, not by laws, but by facts. Medical science has demonstrated that a diseased condition of the brain that gives rise to mental aberration permits of no half-way ground in judging of sanity. Periods of remission cannot reasonably be called "lucid intervals,"

as is often done. After classifying the types of insanity that have been marked out up to the present time, such as the moods, the presence of hallucinations and of delusions, the coexistence of the neuroses and of organic brain-disease, traumatism from excessive use of narcotics, and the mental disturbances occurring from derangement of the organism induced by disease of non-nervous viscera, Dr. Gray called attention to the fact that in paranoia, mania, and melancholia the reasoning powers and the memory are usually intact, yet the patient has undeniable hallucinations and delusions, under the influence of which he commits acts for which he should not be held legally responsible. He cited the case of the paranoiac Dougherty, who imagined himself the beloved of Mary Anderson, and that the world was conspiring to keep him from her, and, in pursuance of this delusion, murdered Dr. Lloyd, of the Flatbush Insane Asylum, and was planning to kill about a dozen public officers whom he believed to be in the conspiracy. Yet he declared himself sane and asserted that he knew the nature, quality, and consequence of his act. He was properly pronounced insane, because his mania was so palpable, although some doubt prevailed in the public mind as to his insanity. The only safe test of the legal and testamentary responsibility of a man lies in an answer to the simple question: Is he insane? If he is, he is not legally responsible, and this question can only be properly decided by competent physicians, not by fine-spun theories of lawyers. Common sense must be applied to such cases rather than metaphysical definitions of mental aberration.

Dr. Edward B. Angell, of Rochester, N. Y., read a paper entitled "Double Lesion of the Brain: Cerebral Cyst and Cerebellar Tumor." The post-mortem examination demonstrated an increase in the development of the brain on the right side, which had to take up the functions of the disorganized left side.

Dr. James G. Kiernan, of Chicago, referred to a case of right hemiplegia with aphasia in an adult in which, by education, speech was regained, but was lost after a second attack. The autopsy showed that the left speech-center had been destroyed in the first attack by hemorrhage, and the second attack destroyed the right.

Dr. J. N. Hall, of Denver, Col., read a paper entitled "Gunnery Developments and the Medical Jurist." He said that newly introduced explosives are rapidly replacing black powder. He described the two most commonly used of these products—the American wood-powder and the Schultze powder. The staining from wood-powder is much less distinct than that from black powder, and the staining from the Schultze powder is even less marked than that from wood-powder. Neither of the two new powders ignites cloth or blotting-paper at so great a distance as does the black powder.

Dr. Harold N. Moyer called attention to the fact that the length of the barrel of the weapon should always be considered in making up tables, and stated that there is always leakage of gases in revolvers. Another interesting point is not only the kind of powder, but also the amount of fulminate in the fixed ammunition, as well as the manner in which it is put into the cartridge, whether fine-grained or practically in a solid mass.

Dr. Frank R. Fry, of St. Louis, read a paper entitled "Sensory Symptoms of Three Syphilitic Cord Cases."

Third Day—June 8th.

Dr. W. J. Herdman, of Ann Arbor, Mich., read a paper entitled "Lesion of the Right Temporo-sphenoidal Lobe." The case reported was at first diagnosticated as one of embolism of the left anterior cerebral artery. The autopsy revealed an extensive hemorrhage anterior to and at the lower extremity of the right lateral cornu. Softening followed, involving the hippocampus major at its lower extremity and the anterior extremities of the superior, middle, and inferior temporal convolutions. The assumption was considered justified that as far as any symptoms observed in this case can be justly referred to the lesion in the right temporal lobe, they tend to show that its function is of the same nature for the left side of the body that Ferrier has found the left temporal lobe to be for the right—that is, a cortical center for hearing and taste.

Dr. Charles K. Mills referred to several similar cases, which appeared to demonstrate that the left upper temporal region is most particularly developed for word-sound, and the right has a minor degree of development of the same function and takes on the function of the left in part, but not entirely, in case of the destruction of the former.

Dr. Charles K. Mills and Dr. G. E. de Schweinitz, of Philadelphia, presented a paper entitled "Hemianopsia and Certain Symptom-Groups in Sub-cortical Lesions." The first case reported presented right lateral hemianopsia, absence of Wernicke's symptom, dyslexia, temporary right hemiparesis, and Jacksonian epilepsy. In the second case there was right lateral hemianopsia, absence of Wernicke's symptom, dyslexia, right hemiparesis, partial right hemianesthesia, partial word-deafness and word-blindness. In the third case there were right lateral hemianopsia, absence of Wernicke's symptom, temporary aphasia, dyslexia, right hemiparesis of spastic type, probably word-blindness. Case four presented left lateral hemianopsia, partial left hemiparaplegia and hemianesthesia, temporary aphasia, epilepsy, Wernicke's symptom. Case five presented lateral hemianopsia, absence of Wernicke's symptom, temporary right hemiplegia, persistent hemianesthesia. Case six presented left lateral hemianopsia, left hemiplegia. Case seven presented right hemianopsia, right hemianesthesia. Case eight presented right lateral hemianopsia, doubtful absence of Wernicke's symptom, slight right hemiparesis. Case nine presented left lateral hemianopsia, absence of Wernicke's symptom at first, paresis of both legs, later right spastic crural monoparesis. Of two cases probably of cortical origin, one presented typical left lateral hemianopsia; and the second, right hemianopsia, with absence of Wernicke's symptom.

Another case was reported of right lateral hemianopsia, followed a year later by left lateral hemianopsia, with absence of Wernicke's symptom, retained macular vision, changes in the color-sense, loss of the sense of location.

A case was also reported that seemed to teach that there may be either functional or organic disturbance of the word-symbol center of the same character as that which produces hemianopsia when the half-center for general vision is destroyed on one side of the brain.

Dr. Thomas D. Crothers, of Hartford, Conn., read a paper on "American Inebriate Asylums."

He said that managers of asylums who teach dogmatically the nature of inebriety and its only true remedies are not far along in scientific work, and asylums that claim large percentages of cures from certain means and remedies are not worthy of confidence. Inebriety is the most complex neurosis of modern research. The gold-cure specifics, so called, are followed by an increased number of insane among those who have used the treatment. This was to have been expected, as the more powerful the narcotic used to stop the drink-symptom the more certain are insanity and profound degenerations of the brain-centers to follow. The asylum care and treatment of inebriates began first in this country, and has grown and extended to all civilized nations of the earth. American asylums have developed the disease-theory and the practical character of physical treatment in institutions beyond that of any others in this field. Asylums in the United States represent nearly all stages of development and early growth, from infancy and childhood, with its feeble conceptions and infantile efforts, to the boastful assumption and over-confidence of youth, on to the dawning truth of early manhood, when reason and judgment begin to reign. A few of these asylums discern similar great truths, which may be stated with confidence as ideals toward which there is a rapid movement. Inebriate asylums must take the place of jails and station-houses. Inebriate asylums should receive the incurable inebriates and make them self-supporting and build them up physically and mentally. Inebriate hospitals should receive the recent cases and place them in the highest conditions of enforced health and vigor, and thus restore a large number to health and sobriety. Inebriate hospitals should be self-supporting when once established. They should be managed on scientific business principles, like military training-schools. Inebriate hospitals should be built with money raised by taxes on the sale of spirits, on the principle that every business should be obliged to provide for the accidents that grow out of it. The inebriate hospitals of to-day are only in the infancy of their work, contending with great opposition and prejudice, misunderstood, condemned, and working against innumerable obstacles. There is an intense personality in inebriate hospitals. Inebriate hospitals and their work are the great new lands which only a few settlers have reached. They are calling to us to come and occupy and thus help the race on in the great march from the lower to the higher.

Dr. Clark Gapen, of Omaha, Neb., read a paper entitled "Lawyer's Criticisms of Expert Testimony."

He said that as at present conducted the trial of a cause involving a medico-legal question is a mere farce, as compared with the trial of a cause involving a pure question of law. The medical expert should be selected by the court as an advisory, and wholly with reference to his special knowledge of the question involved. Medical jurisprudence should be properly taught in the colleges. The so-called chair of medical jurisprudence usually teaches nothing but the mummery of some text-book of ancient times. The proper way is to give a forecast of the legal experience that the student will encounter in the future. He should be taught to be frank, truthful, direct, plain, and non-technical. Students go forth unequipped in this regard. Another cause of the disrespect of medical expert evidence is the common custom of participating in the trial both as counsel and as witness. The court might properly take testimony as to the qualifications of the expert. A good way would be to have lists handed in by each side and let the court choose from the lists. The expert should avoid invading the province of the jury and giving an opinion in the case. The proper course is to put a hypothetic question for the expert to answer.

The following papers were also read:

Dr. Frank P. Norbury, of Jacksonville, Ill., read a paper on "Insanity in the Aged."

Dr. Harriet C. B. Alexander, of Chicago, read a paper on "Acute Mental Symptoms in Children."

The following officers were elected for the ensuing year:

Chairman—James G. Kiernan, of Chicago.

Vice-Chairman—Landon Carter Gray, of New York.

Secretary—F. P. Norbury, of Jacksonville, Ill.

NEWS ITEMS.

Dr. E. O. Shakespeare has assumed editorial charge of the Department of Hygiene and Preventive Medicine of the *Dietetic and Hygienic Gazette*.

A. Kolisko has been appointed Professor of Pathologic Anatomy in the University of Vienna, in succession to Kundrat, recently deceased.

Dr. James J. Levick, a well-known physician of Philadelphia, died June 25th, of cardiac disease, at the age of sixty-eight years. He graduated from the University of Pennsylvania in 1847, and became a resident physician in the Pennsylvania Hospital, and subsequently one of the attending physicians. At a later date Dr. Levick was elected to the staff of Wills Eye Hospital. He was also connected with the Magdalene Asylum. In 1884 he received the degree of Master of Arts from Haverford College. Among his contributions to medical literature were a paper on heart-disease and one on spotted fever.

Books and Pamphlets Received.

Materia Medica and Therapeutics. By John V. Shoemaker, A.M., M.D. Second edition. Two volumes. Philadelphia and London: The F. A. Davis Co., Publishers, 1893.

An Inquiry into the Causes of the Mortality of Diphtheria, and Some Suggestions with Reference to the Treatment of Diphtheria. By Alonzo Bryan, M.D. Reprinted from the Physician and Surgeon, 1893.

Pocket Dose-book. Compiled by John Edwin Rhodes, A.M., M.D. Chicago, Ill.: Sharp & Smith, 1893.

Report on 100 Cases of Ether-anesthesia by Clover's Inhaler. By G. Gordon Campbell, B.Sc., M.D. Reprinted from the Montreal Medical Journal, 1893.

Reports of Friends' Asylum for the Insane, 1893. Philadelphia: George H. Buchanan & Co., 1893.

The Treatment of the Nasal Catarrhs. By William T. Cathell, M.D. Reprinted from the Maryland Medical Journal, 1890.

A Study of Two Cases of Paroxysmal Sneezing, with Treatment. By William T. Cathell, M.D. Reprinted from the Transactions of the Ninety-fifth Annual Session of the Medical and Chirurgical Faculty of Maryland.

The Recrudescence of Leprosy and its Causation. By William Tebb. London: Swan, Sonnenschein & Co., 1893.

ORIGINAL ARTICLES.

HEART-DISEASE OR KIDNEY-DISEASE?[1]

BY JAMES TYSON, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

I HAVE myself so often been mistaken in the first conception formed of the relation between a combination of symptoms for which heart or kidney may be responsible, and have so frequently had occasion to share the difficulty with others, that I have been forced to give the matter some thought; and it seemed to me that so practical and important a subject might also be interesting to the members of this Society.

The difficulties met under these circumstances will, I think, be better appreciated by the brief story of four or five illustrative cases:

CASE I.—O. E., a shop-girl, aged fourteen, was admitted to the Hospital of the University of Pennsylvania, October 31, 1892.

Her mother is said to have had heart-disease, but the family history is otherwise negative. The patient herself had measles in childhood, but, with this exception, reported no illness until that for which she sought admission. This set in apparently only three weeks previously, when she noted that her legs were swollen. Shortly after this she became short of breath. She continued, however, to perform the duties of her position up to the time of her admission to the hospital.

On admission her appearance was most striking. A lustrous pallor pervaded her entire body—in fact, she presented the characteristic waxy hue of chronic renal disease. Her feet and legs were much swollen, as were also the right hand and face. To a less degree she was everywhere edematous, though more so on the right side, on which she mostly lay. The urine was dark-hued, had a specific gravity of 1030, was loaded with albumin, and contained numerous granular casts.

My colleagues, as well as myself, all said: a "typical case of renal disease." The urine-examination seemed scarcely necessary. The diagnosis could be made at a glance. As a matter of course, however, her heart was also examined. The apex-beat, in the third interspace, was forcible and rapid, from 108 to 120, while the respirations numbered from 40 to 43 in the minute. On palpation, a cardiac thrill, systolic in time, could, in addition, be appreciated.

Percussion determined the upper border of cardiac dulness to the left of the sternum, at the superior edge of the third costal cartilage; the right border one inch to the right of the right margin of the sternum. There was, therefore, enlargement of the right side of the heart, as well as of the left. There were the signs of pleuritic effusion on both sides. Auscultation recognized a double murmur, most intense at the apex, with the systolic portion conducted into the axilla.

Here was then a case of mitral disease—regurgitation, and probably stenosis, with right-sided dilatation; but the intense waxy appearance and the pronounced albuminuria led us to believe that there was also positive renal disease, probably subacute parenchymatous nephritis.

The girl was ordered absolute rest in bed, five minims of tincture of digitalis three times a day, and caffein citrate, three grains every four hours. Copious diuresis set in, and at the end of five days the dropsy was almost totally gone. The scanty urine had increased until it reached 62 ounces, while the albumin and the casts had entirely disappeared. The change was almost incredible. I had never seen such a striking one in so short a time. The mitral murmur continued, showing that the heart-disease was the permanent one, and the idea, almost irresistible at first, that there was some special form of renal disease, independent of the passive congestion due to the cardiac disease, was dissipated.

She remained in the hospital until December 24th. Once there was a return of the albumin and a few granular casts, concurrent with an attack of bronchitis, but these again disappeared, and she was discharged seemingly quite well. The diastolic part of the double mitral murmur finally also disappeared, and the heart had been restored to its original dimensions, but the mitral systolic murmur continued, and is likely to be permanent.

CASE II.—F. R. P., a bank-officer, aged forty-two, was seen in consultation with Dr. S. R. Crothers, of Chester, Pennsylvania, on November 19th, 1892. With the exception of typhoid fever, ten years before, and an attack of influenza in December, 1891, he had never been seriously ill. About one year previously to his visit to me he first began to have attacks of palpitation of the heart and shortness of breath, with headache. He was treated for "functional trouble," and improved sufficiently to return to work. In this, however, he overtaxed himself, and at the end of about two months he was again compelled to give up. Although he spent much of the summer at the seaside, there was not improvement sufficient to permit his return to business. All of this time his symptoms pointed to heart-disease, and his own belief and that of his family were that this was his principal, if not his sole illness.

[1] A paper read before the Medical Society of the State of Pennsylvania, at Williamsport, Pa., May 17, 1893.

At the date of his visit to me there were aggravated dyspnea and cough, but the headache, from which he had before suffered so much, had disappeared. There was also nausea, especially in the morning, but at times also in the day, associated occasionally with diarrhea. His complexion was intensely sallow—almost cachectic.

On inquiry, I found that his feet were a little swollen at night, but that this swelling disappeared each morning. Examination of his heart disclosed enormous hypertrophy of the left ventricle, the apex being lowered and displaced to the left. The aortic second sound was accentuated, but there was *no murmur*. The action of the heart was tumultuous, its rate frequent, and its rhythm irregular.

The urine throughout had been copious, light-hued, and low in specific gravity, until a short time before his visit, when it had become scanty and high-colored; but at the time of his visit, through the action of diluents and diuretics, it was increased to 64 ounces in the twenty-four hours. A portion of this examined by me had a specific gravity of 1012, and contained only one-twentieth per cent. of its bulk of albumin, and a small number of hyaline casts.

In this case the prominent symptoms were cardiac, in contrast with Case I, in which the most striking symptoms pointed to the kidneys as their source, and in fact were at the time caused by the renal complication. Yet the former was primarily a case of renal disease, and the latter one of heart-disease.

This is a state of affairs that supervenes on an interstitial nephritis, a gradual hypertrophy of the left ventricle, the rationale of which is not perfectly agreed upon, but which I am inclined to look upon as a compensatory hypertrophy, maintaining the individual in tolerably good health until compensation begins to fail, when the symptoms of cardiac distress described set in, and increase until death takes place, as in this case, suddenly, from simple cardiac failure, or, as is perhaps more frequent, from uremia.

In this instance, therefore, a case of primary renal disease was overshadowed by cardiac symptoms in so marked a degree as to cause the latter to be overlooked.

CASE III.—A. G. B., a retired merchant, aged sixty-two, consulted me first on the 16th of April, 1892. He had a clear family history of gout, his father having been gouty years before his death, and dying suddenly. The patient himself had been subject to attacks of gout for a number of years, and had tufaceous deposits in his knuckles. He had an attack of influenza in the early part of 1890, and another in May, 1891; but during the year previous to his consulting me he had been more than usually exempt from gout.

Albuminuria was discovered by Dr. Pepper in May, 1891. Following this the patient spent the summer in Europe. While in Europe the albumin disappeared, and continued absent until a few days before he consulted me, when its presence was discovered by his son, a medical man. He also noted at this time a little dyspnea on exertion, but with these exceptions felt as well as usual. His last evident attack of gout was on board ship, in the autumn, while returning from Europe.

At the time of his visit to me, in April, 1892, I examined his urine, morning and evening samples. Each contained one-tenth of its bulk of albumin, but I found no casts in either sample. The morning urine had a specific gravity of 1016; the evening, of 1014. I concluded promptly that I had to do with a case of chronic interstitial nephritis of gouty origin.

In June, following his visit to me, the patient again went to Europe, and returned late in September, 1892. He had a couple of slight attacks of gout during his absence, and a little oppression in breathing on shipboard, so that he had to sit up in his berth. During the month of June there was some irregularity of action of his heart, which he ascribed to flatulence. With these exceptions, he considered his health even better while in Europe, in the summer of 1892, than in the previous summer.

On November 21, 1892, he again consulted me. He complained of flatulence, and of what he termed wind pressing on his heart. This prevented him from lying down in comfort. He also thought that it caused cough. On the day before his visit he first noted a little swelling of his feet.

I now examined his urine again. It was dark-hued, contained one-tenth of its bulk of albumin, and this time I found a few hyaline casts. There was also a little swelling about his ankles, and auscultation disclosed an evident mitral systolic murmur. I prescribed rest at home (he had been attending to some business), salicylic acid, pepsin, and aromatic powder for the flatulence; also hot water before meals; and for the dropsy, a pill containing digitalis, quinine, squill, and nux vomica. In a few days the edema had disappeared, and the dyspnea was partially relieved. A few days later both symptoms returned, and although again relieved for a time, they proved ultimately intractable. There was dulness to the right of the sternum. Evidently the right ventricle was yielding. The urine became more scanty, the albumin increased, as also did the casts, and the patient died suddenly December 20th.

CASE IV.—John W., a colored laborer, fifty-two years old, was admitted to the Hospital of the University of Pennsylvania, April 18, 1893. His family history was negative. He had had a bad attack of typhoid fever thirty-five years ago. Eight years ago, while working in a brick-yard, he suddenly fell, and was unconscious for about four hours. With returning consciousness came unimpaired muscular power; but four years later he awoke one morning completely paralyzed on his left side, without any evidence of anything else happening in the night. At the end of three days, however, he began to regain power in the arm and leg of the affected side, and in three months was able to move around with the aid of a cane. His condition in this respect has

been improving steadily, but two years ago he noted that he was short of breath, and last winter this symptom grew worse, while edema of the legs was superadded. These symptoms finally became so aggravated that he entered the Philadelphia Hospital, whence, after six weeks, he was discharged, greatly relieved.

Two weeks previously to admission to the University Hospital he again became ill, the chief symptoms being enormous swelling of the legs, orthopnea, and a dry, hacking cough, very troublesome at night. On admission we noted also irregularity of the heart, hypertrophy of the left ventricle, and an easily recognizable mitral systolic murmur. There was also the remnant of the left-sided paralysis, and on this side the edema was much greater than on the right side. There were the signs of effusion in the left pleural sac, and the percussion-boundary of the liver indicated some enlargement.

The urine was albuminous, containing one-seventh of its bulk of albumin, but no casts were found.

The diagnosis here made was mitral regurgitation, a diagnosis that was thought to be sustained by the enlargement of the liver. Treatment proved ineffectual, and the man died less than three weeks after admission.

At the necropsy there was found enormous eccentric hypertrophy of the left ventricle, with dilatation of the right ventricle, both ventricles, and especially the right, being distended with blood. The heart weighed 1000 grams, with the blood in it, 750 when emptied, the normal weight being about 337 grams. The *mitral leaflets were a little thickened, but essentially normal.* The aortic cusps were normal, as were also the valves of the right side of the heart.

There was a large effusion in the left pleural cavity, as recognized before death, and a patch of congestion in the lower part of the left lung. The liver weighed 1285 grams, and was *not*, therefore, enlarged, the normal weight being from 1550 to 1860 grams.

Both kidneys were enlarged, the right weighing 210 grams, the left 220 grams, the normal weight being from 130 to 150 grams. The cortices especially were widened, and the seat of chronic parenchymatous nephritis, which, in the light of the autopsy, I regard as the cause of the hypertrophy of the left ventricle.

I have selected, from among many cases, these four of combined cardiac and renal disease, in all of which there was, at the beginning, and in some throughout life, more or less erroneous conception of the exact state of affairs. The first case, that of the shop-girl, aged fourteen, was supposed to be a case of chronic parenchymatous nephritis, while further study showed it to be one of primary valvular disease of the heart, with secondary passive congestion of the kidney.

The second case was one of chronic interstitial nephritis, with hypertrophy of the left ventricle, in which all of the symptoms pointed to primary heart-disease, but the true nature of which was easily revealed upon closer study.

The third case was a more complex one than either of the others. An ancestry of gout; a personal history of much gout; an albuminuria, at first small; absence at first of casts, and then sparse casts, all pointed to gouty kidney, a supposition by no means weakened by the oppression and dyspnea, symptoms that almost always supervene when the hypertrophied left ventricle of chronically contracted kidney begins to fail. On the other hand, the evident mitral murmur, the moderate degree of hypertrophy of the left ventricle, the stretched right ventricle, the irregular heart, the gastric catarrh, and the dropsy, pointed to a condition of mitral regurgitation, which, I cannot but think, was also present, a view in which I was also sustained by Professor Da Costa, who saw the case with me. Yet the problem was a difficult one, and the question, "heart or kidney?" was carefully debated. It seemed to us that in this case doubtless both organs were affected independently of that interdependence that always exists between these two important organs. That is, there were interstitial nephritis and endocarditis, both the result of the same cause—gout—and the coöperation of these two conditions accounted for the intractableness of the case. Unfortunately, in this case there was no autopsy to settle the question, and it must always remain a matter of probabilities.

That such a state of affairs does occur is shown by the following interesting case:

Case V.—C. K., a Russian coal-miner, aged twenty-eight, from Schuylkill County, was admitted to the Hospital of the University of Pennsylvania, April 12, 1893. On account of his total ignorance of English no family or previous personal history could be elicited, except the indefinite statement that his feet had been swollen for ten years, and yet that he was perfectly well up to three weeks before admission, and working in a coal-breaker.

On admission he was gasping for breath, in an unpleasant, grunting manner. His heart was extremely irregular, and at times beat so rapidly that it could scarcely be counted. It was noted soon after admission at 144, again at 166. His respirations on admission were 36; and when his pulse was 166, the respirations were noted at 46. His temperature was normal. His belly was distended with fluid. There was edema of the feet and legs—in fact, general anasarca—and he lay in such a stupid state that it was difficult to get any information from him. On admission he was expectorating a blood-stained mucus, regardless of time or place.

Physical examination revealed the liver to be much enlarged and tender; the heart not much enlarged, but acting tumultuously, and no murmur could be detected. Subsequent examination showed the right boundary of the right ventricle at the right edge of the sternum, indicating enlargement of the

right heart. The examination of the lungs, on admission, was not satisfactory, because of the extreme illness of the man, and his disgusting, filthy state. The urine was scanty, high-colored, and bile-stained. It contained only a moderate amount of albumin, from one-twentieth to one-eighth of its bulk, but numerous hyaline and pale granular casts.

Under full doses of the infusion of digitalis he improved quite rapidly, the pulse and breathing rate coming down gradually. The rhythm of the pulse also improved, and the anasarca diminished. On the 30th of April his pulse had fallen to 64, and my note reads: "Although the pulse is slow and forcible, no murmur is detectable, yet we feel sure there is mitral regurgitation." His improvement was so great that he was even allowed to sit up. On May 5th, his temperature began to rise, and concurrently his breathing to be more frequent. On the 11th the signs of fluid in the left pleura were apparent (probably had shown themselves a couple of days earlier, because, on account of difficulties, he was not examined daily). The respirations were 50, but the pulse did not rise above 108, and for the first time a distinct mitral systolic murmur was audible. On the 14th it was thought a murmur was heard, but repeated examinations, even when his heart was at its best, failed to detect anything definite until the 11th. The man died suddenly a day later.

The necropsy was most instructive. The lesions were numerous, but most interesting in this connection was the association of extreme mitral stenosis, in the shape of a button-hole mitral orifice, and a pair of typical large white kidneys, beginning to undergo contraction. There was also enlargement of the heart, more especially in the direction of the right ventricle, as recognized before death, associated with marked dilatation of the left auricle. There was a left-sided empyema of recent origin, as shown by a fresh layer of thick lymph, probably the immediate cause of death; anthracosis, or miner's lung, with cavities; an enlarged hypertrophically cirrhotic liver; an enlarged spleen with two pyoid sacs, probably softened infarcts.

The fourth case was a complete surprise in the light of the autopsy; yet I am doubtful whether, with the situation repeated, I would make a different diagnosis. The distinct mitral systolic murmur and the extreme anasarca, the scanty urine and pleural effusions, all combined to favor the idea that there was mitral regurgitation, while the fact that the man had had two seizures, best explained on the supposition of cerebral embolism, of which a cardiac embolus is the most common cause, seemed to add all that was required to make the diagnosis absolute. One symptom only might have suggested a renal origin, and that was the degree of hypertrophy of the left ventricle, without aortic disease. Mitral regurgitation, while causing hypertrophy of the left ventricle, seldom produces the extreme hypertrophy that attaches to aortic valvular disease or chronic renal disease without aortic valve disease. At the same time the extent of this hypertrophy was not appreciated before death, because of the difficulty of investigation occasioned by the naturally thick chest-walls, further thickened by anasarcous infiltration. Under the circumstances, the mitral murmur is best explained on the supposition that there was mitral regurgitation consequent upon dilatation of the hypertrophied left ventricle.

Yet, notwithstanding the difficulties encountered in the separation of heart-disease from kidney-disease, there are certain points that, if borne in mind, aid in the discrimination. These points, already referred to, deserve, in conclusion, to be recapitulated: First, the conditions most likely to be associated or confounded are mitral disease on the one hand, and chronic parenchymatous nephritis on the other, or the last stage of interstitial nephritis, when the urine, from having been copious and light-hued, becomes scanty and dark-hued, because of failing cardiac power.

Chronic parenchymatous nephritis.	Chronic interstitial nephritis. (Last stages.)	Mitral Disease.
Urine scanty and high-colored; high specific gravity; highly albuminous.	Urine though scanty is still light-hued, and has low specific gravity; moderately or slightly albuminous.	Urine scanty and high-colored; high specific gravity; moderately or slightly albuminous; rarely highly albuminous.
Numerous granular, dark granular or fatty casts.	Few casts, and these hyaline or slightly granular.	Few casts, hyaline or slightly granular.
Much dropsy.	Little dropsy as a rule, though when heart fails dropsy may be marked.	Much dropsy; effusion into serous sacs.
No mitral systolic murmur.	No mitral murmur.	Mitral murmur.
As a rule no hypertrophy of left ventricle, which may, however, be present at times.	Always marked hypertrophy of left ventricle, except in persons feeble and cachectic at the outset; this without aortic murmur.	Moderate hypertrophy of left ventricle; hypertrophy of right ventricle.
No enlargement of liver.	No enlargement of liver.	Enlarged and tender liver.
No signs or symptoms of arterio-capillary fibrosis.	Symptoms and signs of arterio-capillary fibrosis may be present.	No arterio-capillary fibrosis.
No retinitis albuminurica.	Retinitis albuminurica may be present.	No retinitis albuminurica.
No history of gout.	History of gout, lead-poisoning, or free eating and drinking.	Seldom a history of gout, alcoholism, or free eating and drinking.
Seldom a history of rheumatism; more frequent of infectious disease.	No history of rheumatism or infectious disease.	Probable history of rheumatism or infectious disease.
Uremia infrequent.	Uremia frequent.	No uremia.
Partial response to treatment.	Doubtful response to treatment.	Generally prompt response to treatment.

These points of diagnosis refer more particularly to uncomplicated cases. With complicated cases the

difficulty is greatly increased, and the decision must be one of probabilities. A fact of great value in my judgment in favor of a primary and advanced kidney-disease, is the failure of heart-tonics like digitalis to produce diuresis, even though the pulse-rate is decidedly reduced by the action of the remedy.

Now, what is the practical bearing of these considerations? I answer, not so much in the direction of therapeutics as in that of prognosis. For, happily, the treatment of these conditions is essentially the same, and to this subject I have given very full consideration quite recently elsewhere.[1] In the matter of prognosis, however, it is of the extremest importance. For in cases of pure mitral disease, not too far advanced, the most favorable prognosis may be given, as evidenced by our experience with Case I. In the stage of renal disease under consideration, however, and in the combined form with actual structural change in both heart and kidney, the prognosis is very unfavorable, and to mistake the one condition for the other, and to prognosticate accordingly, may seriously jeopardize one's reputation.

SIMPLICITY IN THE TREATMENT OF FRACTURES.[2]

BY JOHN B. ROBERTS, A.M., M.D.,
OF PHILADELPHIA.

THE essential factors in the treatment of broken bones are, undoubtedly, the early replacement of fragments, the prevention of recurrence of displacement, attention to the condition of the soft parts, and due consideration of the patient's general health. After the reduction has been satisfactorily accomplished, displacement may recur through the action of gravity, muscular contraction, or the restlessness of the patient; and the surgeon must guard against such recurrence by applying some form of fracture-dressing that will retain the fragments in proper position. The best form of dressing will, as a rule, be that which corrects the tendency to displacement and, at the same time, steadies and immobilizes the limb. Special tendency to displacement varies with the line and position of the fracture, and should be recognized by the surgeon before he decides upon a form of dressing.

Fracture-dressings may be classed under three divisions: First, those that exert moderate continuous traction, or maintain the extension that was applied when the fracture was first adjusted; secondly, those that, by virtue of their rigidity or fixedness, resist retraction; and finally, those that, by virtue of their inflexibility, prevent angular or lateral displacement, by furnishing lateral support to the fracture.

These statements, which are almost axiomatic, will probably meet with the approval of all the members of the Society; but it is more than likely that, in a general discussion of the subject, there would be advocated a dozen different ways of treating the same fracture. It seems to me that surgeons often lose sight of the fact that simplicity in fracture-dressings is as much a surgical virtue as simplicity in the form of instruments used in surgical operations.

Simplicity in the treatment of fractures is often neglected because of an obsequious reverence for the names of former surgical teachers, which have become attached to a splint, or method of dressing. It is stated that legends and traditions connected with historic places never die; it is, unfortunately, true that surgical traditions have a similar lasting and often deleterious influence upon the progress of surgery. Illustrations of this are seen in the present use of Bond's splint for fracture of the lower end of the radius, an appliance founded upon an erroneous understanding of the nature of the injury, and one of the worst splints that could be used in the treatment of such a fracture. Physick's long splint for fracture of the femur is still used in this injury by many surgeons, who fail to realize that a more modern method of dressing is less troublesome to the attendant and more comfortable and safe for the patient. Desault's dressing for fracture of the clavicle has now no value except as a puzzle with which to entangle unhappy students under examination; yet it is probably still employed.

Many books are filled with elaborate descriptions of fracture-dressings, whose number seems to be limited only by the patience of the author. Hamilton's *Treatise on Fractures* is so full of these complicated splints and devices that the young practitioner must be hopelessly lost in selecting a method for treating a fracture under his immediate care. Individuals, as well as races, are born with mental characteristics that drive them to invent and advocate complicated methods in all the pursuits of life. The English and German surgeons perhaps illustrate this tendency to an extreme degree. Some American surgeons, partly from individual traits and partly from over-developed imitative faculties, are led in the same direction.

A truly wonderful illustration of this perversion of the mind is found in Bardenheuer's *Guide to the Treatment of Fractures*. I show a single illustration taken from his book in proof of my statement. Could anything be more preposterous than the

[1] "The Relations between Renal Disease and Disease of the Circulatory System," International Clinics, vol. iv, second series, 1893. "Treatment of Chronic Valvular Disease of the Heart," Therapeutic Gazette, April 15, 1893.

[2] Read at the meeting of the Medical Society of the State of Pennsylvania, at Williamsport, May 17, 1893.

method by which a patient with an ordinary fracture of the lower end of the radius is here treated? He is shown confined to bed, with weights and pulleys attached to his arm and hand so as to make traction in five different directions. Such a method of dealing with an injury, which ordinarily needs scarcely any splint, is a travesty of modern surgery. That even an American can accept such complicated dressings is shown by a visit to the wards of some of our large metropolitan hospitals. I recently saw in a hospital in a neighboring city a patient with a fracture of the thigh. The dressing was a Physick's long splint, combined with the extension-apparatus of Buck, and I think a plaster-of-Paris incasement —that is, this afflicted patient had about as much apparatus applied for his single fracture as would be required for the treatment of three patients with a similar injury. Any one of the appliances would be sufficient for an ordinary fracture of the femur.

Physicians coming to Philadelphia are, I think, often surprised at the simplicity of the dressings used in some of our hospitals. It is certainly gratifying to know that we do work in a less complicated manner than is the case in many other cities.

Another reason for a want of simplicity in fracture-dressing is that students are often taught during their pupilage that each fracture has its special splint; hence, they do not realize that the same form of dressing, with very slight alteration, will often answer for fractures in different parts of the body. I have never forgotten an expression used by Prof. Chiene, of Edinburgh, who told me that he disliked ready-made splints, as he did ready-made trousers—they never fitted.

Few will dispute the desirability of simplicity, provided that simple measures meet the indications and fulfil the surgical objects. Simple dressings are always attainable; they are cheap, and they are usually much more comfortable to the patient than more elaborate appliances. The latter are much more liable to become displaced and cause discomfort, and their intricacies are much less likely to be understood by the patient's friends or the hospital resident. The complication also tends to make the surgeon hesitate about removing the dressing, as much time, considerable assistance, and no little skill are demanded in its replacement. For this reason complicated dressings are likely to be changed less frequently than simpler ones, and the progress of the fracture less often noted. I am quite convinced that simple appliances that are readily removed and easily adjusted tend to yield better results, because of the more frequent examination and inspection given the injured bone.

I would obtain simplicity by disregarding all the unnecessary portions of dressings, and by selecting simple articles for retaining the fragments in apposition. The primary bandage often applied to the limb before the splint is adjusted is unnecessary and sometimes harmful; it is seldom used by practical surgeons of to-day. Embrocations of lead-water and laudanum, and of similar drugs, supposed to lessen the amount of inflammation at the seat of fracture, should be discarded, as they have no potent influence upon lessening the inflammatory exudate, and may, perhaps, by maceration of the skin, lead to blebs on the surface of the limb. Proper coaptation and freedom from muscular contraction are the factors most needed in the treatment of the inflammatory condition. With omission of the primary bandage and the embrocations, which some surgeons cling to as a sort of fetich, there is nothing to be applied to the fracture but the retentive apparatus. This should be of the simplest description. The surgeon who has sufficient individuality to refuse to pay for a carved or moulded splint of metal offered by an instrument-maker will seldom have difficulty in dressing a fracture in a simple manner.

The form of displacement and the character and seat of the fracture will give a hint to an observant surgeon as to the kind of apparatus to be used. Anything that tends to maintain the proper contour of the bone after reduction is what is needed. If wooden splints are used, they should be very light and seldom thicker than the lid of an ordinary cigar-box. Heavy splints, with much padding, are uncomfortable to the patient because of their weight and heat. In most fractures comparatively little strain is likely to be thrown upon the broken bone during treatment; hence, a splint with a moderate degree of rigidity is all that is needed to prevent displacement.

There is no question that the best splints in use are those that are moulded to the limb after reduction of the fracture. These fit any inequality of the surface without padding, and can, therefore, be very light, and are worn with comfort. Moulded splints are most readily made from butter-cloth, or cheese-cloth, dipped in plaster-of-Paris, paste, or glue. They are readily prepared, and can be moulded to the form of the limb without giving the patient pain. In some cases almost no apparatus is needed, because the parts may be put in the position that places the displacing muscles at rest and that insures proper coaptation of the fragments; for example, a fracture of the fibula, in which there is very little tendency to displacement, may be treated by simple bandaging, or even this may be dispensed with, because the parallel tibia makes an efficient splint. In some fractures of the phalanges an adjoining finger or toe acts as a good splint, or the finger of a glove, made rigid, will keep the parts in good position. A little additional firmness can be given to the glove-

finger by painting it with glue or mucilage. In the same way a stocking may be used as a splint, by making it a little more rigid with starch, plaster-of-Paris, or other hardening material.

The rapidity with which plaster-of-Paris, mixed with water, solidifies makes it, by all odds, the best material for moulded splints. Felt, or gutta-percha, may be softened by dipping it in hot water, and may then be moulded to the part; but these materials are not so easily obtained as gypsum or plaster-of-Paris, which is always to be found in any country store. Strips of gauze, or other woven fabric, may be converted into excellent splints by saturating them with plaster-of-Paris and water. Eight or ten of these strips when applied to a limb soon become hard and will hold it in position. Lateral, anterior, or posterior splints of any shape may thus be made and are to be held in place by a roller bandage. The plaster-of-Paris must be kept dry, for if it has absorbed moisture it will not set. The setting may be retarded by adding a little dissolved glue or borax, or cream of tartar, or by the use of cold water in making the mixture. Setting may be hastened by the use of hot water, or by adding a little common salt to the water. It takes very little skill to cut V-shaped pieces out of the gauze and to overlap the edges when the corners are to be turned; a moderately good surgeon can make a splint of this kind fit perfectly. In compound, or open, fractures, openings can be left or made in such splints. Strips of metal, to further stiffen the splint, or metal rings, for supporting a limb, may be incorporated in the layers of gauze and gypsum.

Sometimes we can use another part of the body to maintain apposition of the fragments. Thus, in fractures of the upper part of the humerus the thorax may be used as a splint, when the arm is bound by a bandage to the chest. Fractures of the lower jaw are usually treated by using the upper jaw as a splint.

In the treatment of open, or compound, fractures less simplicity is possible in the first dressing; but the surgeon who is fully imbued with the doctrines of antiseptic surgery will usually be able to convert fractures of this kind into what are practically closed ones. Thoroughly laying open the injured regions, scraping out all particles of dirt, scrubbing the parts well with soap and water and a nail-brush, and providing for removal or asepticity of all accumulations of blood, will enable him to put a dry antiseptic dressing and a splint upon the injured extremity, with the conviction that the wound will probably go on to recovery with very little variation from the clinical course of uncomplicated fractures in the same region.

It will perhaps aid in the discussion of this subject, if I give illustrations of simple methods of treating common fractures. It will be understood, of course, that my personal preferences are shown by these illustrations; but, naturally, there are many other equally simple methods of treating the same injuries, which may be adopted by other surgeons. These descriptions necessarily refer to such fractures of bones as are ordinarily seen, and not to cases of unusual severity.

Fractures of the clavicle are usually satisfactorily treated by Sayre's adhesive-plaster dressing, consisting of two long strips of plaster, which act by drawing the upper part of the humerus backward, fixing the lower angle of the scapula, and pushing up the elbow. Fractures of the clavicle unite with less deformity, as a rule, if the patient is kept upon his back for a week or ten days, so that the scapula is held in position by the weight of the body pressing against a hard, smooth mattress. The supine position, with arm and forearm thrown across the patient's chest, usually allows the fragments to fall into proper position. Such recumbency for a few days gives a chance for the tissues surrounding the seat of injury to become more or less rigid with inflammatory exudate, and there is, therefore, less danger of recurrence of the deformity when the patient is allowed to walk about with Sayre's dressing applied to the injured region.

Fractures of the upper end of the humerus are successfully treated by putting a towel in the axilla, and then bandaging the upper arm to the side of the chest, having the forearm, which is otherwise free, carried in a sling.

Fractures of the middle of the shaft of the humerus are well managed by an internal angular splint, preferably made of gauze and plaster-of-Paris. Fractures of the lower end of the humerus are best treated with the elbow in the extended position, so as to retain the carrying function of the arm. I prefer holding the elbow in this position by a splint of wood having the obliquity of the normal axes of the arm and forearm or by means of a gypsum splint.

Fractures of the forearm require an anterior and a posterior straight splint, which should be neither too wide nor too narrow. Fractures of the lower end of the radius usually require nothing but a wristlet, or band of adhesive plaster, carried around the lower end of the bone to restrict the movements of the wrist-joint after reduction. Where there is unusual comminution of fragments a straight wooden splint, about six inches long and an inch wide, placed on the back of the wrist, is all that is required. Fracture of the olecranon demands scarcely more than a wooden splint about eight inches long and one inch wide, in front of the elbow, to prevent flexion. Fractures of the femur, whether of the neck or shaft, or above the condyles,

can generally be well treated by permanent traction, made by attached adhesive plaster and a weight fastened to a rope going over a pulley at the foot of the bed.

By altering the direction of the traction, the surgeon will find this method satisfactory in all ordinary cases. Sand-bags at the sides of the femur, to prevent displacement, or a short splint of binder's board around the thigh at the seat of fracture, is the only additional apparatus likely to be needed. Sometimes this can be omitted. For fractures of the tibia and fibula, a fracture-box, or plaster-of-Paris splints meet all the ordinary indications.

SCIENTIFIC OBSTETRICS IN PRIVATE PRACTICE.[1]

BY EDWARD P. DAVIS, A.M., M.D.,
PROFESSOR OF OBSTETRICS IN THE PHILADELPHIA POLYCLINIC; CLINICAL LECTURER ON OBSTETRICS AND GYNECOLOGY IN JEFFERSON MEDICAL COLLEGE, ETC.

IF one were asked the meaning of the word "scientific," a proper definition would be found in a phrase indicating the possession and dissemination of knowledge. A scientific journal is one that contains and disseminates knowledge of the subject of which it treats. Modern medicine is a science in so far as it contains valuable knowledge concerning human life and disease, and scientific obstetrics is the theory and practice of this branch of medicine, characterized by accurate knowledge.

In this one point of the possession or absence of accurate knowledge rests the difference between the obstetric practice common in the United States twenty-five years ago and the theory and practice taught at the present day. Impressed with the ability of nature to deal successfully with the emergencies of labor, the practitioner who attended obstetric cases has been wont to comfort himself with the axiom that labor is a natural process, of which he need not seek to ascertain too minutely the details. The condition of pregnancy he regarded as naturally normal, and hence without especial tendency to disease. The lying-in period was to him a natural stage in the life of the individual, and required at his hands no especial scrutiny. An accurate diagnosis as to the factors present in a given labor was rarely made, unless some serious emergency arose.

There have been many reasons for this condition of affairs. The comparatively recent discovery of anesthetics placed at the disposal of the obstetrician a means of diagnosis of inestimable value. The employment of antiseptics has rendered possible manipulations for the diagnosis and treatment of labor that formerly were impracticable. Methods of diagnosis are now commonly taught and practised that, at the period mentioned, were only to be seen in practice in the large hospitals of Europe. Modern obstetrics has, then, great advantages in its opportunities to acquire thorough knowledge of the patient and of her labor, and this, too, without the infliction of additional pain, or the incurring of added risk to life. The characteristic of modern obstetrics is its scientific element, as shown in the accurate knowledge that it requires concerning matters formerly thought to prosper inevitably through the kind coöperation of Nature.

Scientific obstetrics is the rule in the modern hospital, but it is often "honored more in the breach than in the observance" in private practice. The reasons for this are many. First, among all, is the common belief, derived largely from physicians and nurses, that, because labor is a natural process, it is bound to proceed successfully without intelligent supervision. If this is true, why should a patient tolerate palpation, auscultation, or pelvimetry; or why should she take an anesthetic when the mechanism of labor is interrupted, and a thorough examination of the condition present becomes necessary? A common belief that has descended from the days of the early craniotomist, or man-midwife, as he was termed, is that any interference with labor means, practically, the use of forceps, and hence the objection to critical examination in an emergency. Again, it not infrequently happens that a complicated labor terminates spontaneously, and apparently with success to mother and child. It does not occur to the patient and her friends that complications may have arisen, by reason of the long continuance of the spontaneous labor, that could have been avoided had intelligent interference been practised.

There is especial need for scientific obstetrics in private practice, because the practitioner is more directly responsible for the condition of his patient than when he is engaged in hospital practice. He lacks in private the experienced observation of trained nurses; he misses the intelligent coöperation of resident physicians; and experiences the great disadvantage that the absence of order and discipline, so common in a private house, entails upon him. It is, therefore, especially necessary that he gain thorough knowledge of his patient by personal observation and study, and this knowledge is the essential of scientific obstetrics. The fact that the best results in obstetric practice are observed in hospitals, draws attention to the need for scientific work in private cases.

Omitting a consideration of the minor details of private obstetric practice, we urge the importance of a thorough examination by the practitioner of all pregnant patients. We are well aware of the fact

[1] Read before the Section on Obstetrics, American Medical Association, Milwaukee, June, 1893.

that many cases are not seen by their attendants until labor is far advanced, and no opportunity has been given to examine the patient during pregnancy. This is growing to be, however, less the case than formerly, and especially in first pregnancies, when the natural dread of an untried experience brings the patient to the physician comparatively early. This scrutiny of the pregnant patient should be directed especially to ascertaining the condition of the organs of elimination, and the success attending their action. The examination of the urine should be an invariable practice, and valuable information will be given by ascertaining not only the presence or absence of albumin, but by careful microscopic study of the sediment, and also an estimation of the amount of urea excreted. In the Maternity Department of Jefferson Medical College Hospital we have for some time derived valuable information regarding a patient's eliminative powers by ascertaining the quantity of urea excreted. The presence of albumin is of itself a trifling matter, unless the microscope reveals evidence of decided structural change in the kidney.

At or after the seventh month of pregnancy it becomes the duty of the attending physician to ascertain the mother's size, and the relative size of the fetus and the position that it occupies in the mother's pelvis. This is a procedure commonly thought unnecessary, and reserved for the lectures of those who teach obstetrics. That such is not the case is well exemplified by two fatal cases, seen by me recently in consultation, in both of which embryotomy upon the dead fetus was necessary. Two well-developed male children were sacrificed to a lack of diagnostic skill on the part of the medical attendant, and to complete the unfortunate history of those two cases, the lives of the mothers were lost on account of the stupid laziness of the physicians, who neglected to use antiseptic precautions during labor. In both cases the child had perished before the consultation, and the embryotomy was performed to spare the medical attendant from reproach and criticism for his failure to deliver the mother. These four lives could have been saved had proper precautions been taken.

The practice of general medicine, including obstetrics, in country towns or villages, often taxes to the utmost the skill and wisdom of the so-called "country doctor." As a result, he has a range of experience unknown to his city brother, and becomes by natural development more assured, self-reliant, and efficient. He is the man who, above all others, can appreciate the value of any method of practice that shall add to the positive knowledge he has of his patient. We do not ask him to provide himself with elaborate or costly pelvimeters, or instruments for diagnosis, but, as is our custom in lectures at the Philadelphia Polyclinic, we do urge upon the general practitioner a knowledge and practice of palpation, auscultation, and of such a method or methods of estimating the size of the mother's pelvis and the relative size of the fetus as may be within the scope of his possibilities. No student graduates from a well-appointed medical college who is not in the possession of this knowledge, and certainly the general practitioner already established cannot afford to be behind the recent graduate in his resources. The objections urged against the examination of pregnant patients, including the measurement of the pelvis, are based upon needless exposure of the patient, or rude and unskilful manipulation. We have yet to find a private patient, of whatever station in life, who offers the slightest objection when her physician asks that he be given an opportunity to acquire a knowledge that shall the better enable him to care for his patient, particularly if, by so doing, he subjects her to no exposure, nor to tedious and painful manipulation. The abdomen of the patient may remain covered by one thickness of cotton or linen, without in the least inconveniencing the physician, and medical students under my instruction are taught to make their examinations in this manner.

One of the great advantages accompanying this mode of practice is the lessening of vaginal examinations, which are a source of considerable danger to the patient. It is perfectly possible by palpation alone to follow the head of the child as it descends through the pelvic canal and impinges upon the pelvic floor. The character and efficiency of the pains of labor may also thus be accurately observed, and oftentimes valuable assistance can be rendered by external pressure gently and judiciously applied.

When the mechanism of labor is interrupted, a thorough internal examination is at once indicated. This is often impracticable without the administration of an anesthetic. The practitioner should be prepared to interfere for the assistance of the patient. Forceps should be prepared and ready. The rectum and bladder should be emptied, and, while it is not necessary to state to the patient that an operation is to be performed, yet, while she is under the influence of the anesthetic, it may be found wise to terminate the labor. It is often impossible to accurately diagnosticate a faulty position of the head without an anesthetic, the resistance and suffering of the patient being so great that sufficient of the hand cannot be introduced to make a thorough examination. When, however, such an examination has been made, and before the examining hand has been withdrawn, the forceps may often be accurately applied to the sides of the child's head, and the labor brought to a successful termination. In other cases, version and extraction may be found neces-

sary. In either event, examination of the patient under anesthesia will spare her hours of suffering, and will often save the life of an infant, and sometimes that of the mother.

The same thoroughness in treatment should obtain in the diagnosis and treatment of injuries to the genital tract. By the term "laceration of the perineum," we understand a solution of continuity that extends more deeply than the posterior commissure or fourchet. We are aware that a laceration in the median line may extend beyond the fourchet, and still not impair the supports of the uterus to any appreciable degree. When we read and hear of large numbers of cases of labor in which no laceration of the perineum has occurred, we are impressed with the fact that those who record such extraordinary experiences either consider that a laceration of the perineum usually extends into the rectum, or else that they did not accurately examine the cases. The examiner may be readily deceived by a superficial examination by the finger only of the genital canal, soon after labor. Clotted blood often fills a torn surface, giving to the finger the same continuity of smoothness that marks the uninjured mucous membrane. It is only by the thumb and finger, one inserted in the rectum, or, better still, by actual inspection, that the condition of the genital tract after labor can be accurately ascertained. Considerable observation of labor-cases, and the careful employment of the best-known means for preventing laceration of the perineum, have convinced me beyond reasonable doubt that such an injury is inevitable in many cases. It is negligent not to discover it; it is lazy and dishonest not to endeavor to repair it.

Fortunately, in these matters, public sentiment is demanding the advantages of scientific obstetrics. We recently had occasion to tell a young woman that she had sustained a laceration of moderate extent that ought to be closed. She said that if such was the case, she earnestly desired that it be at once repaired, as her sister had suffered from the neglect of her physician in not suturing a similar laceration. We are furthermore helped in dealing with these questions by the fact that experience shows us that excellent results may be obtained as late as twenty-four or thirty-six hours after the occurrence of a laceration. It is far better practice to give the patient and physician twenty-four hours' rest after a trying labor, and then, under anesthesia, or with the use of cocaine, close a laceration under favorable circumstances, than to further exhaust a weak patient, and with poor light and laboring under great fatigue, to improperly perform the physician's duty. If torn surfaces are found glazed over, the simple expedient of scraping them with the blade of a pair of scissors, or with a curet, will suffice to secure union by first intention.

It is burdening you with a trite observation to speak of the importance of obstetric antisepsis or asepsis, and yet the same reasoning that enables the practitioner to assert that in his 1000 cases he has never had a lacerated perineum, leads him likewise to claim that his 1000 cases he has never had a case of puerperal septic infection. He may have avoided signing a death certificate for a patient recently delivered, the certificate bearing the words "peritonitis," "blood-poisoning," "inflammation of the bowels," or "puerperal fever"; but cases occasionally perish some weeks after labor, with "jaundice," "pneumonia," "congestion of the liver," or "malaria," that, on closer study will be found to be the results of puerperal septic infection. The faithful practice of aseptic or antiseptic precautions greatly lightens the load of responsibility that the practitioner of obstetrics must carry.

Not the least of the advantages derived from the scientific practice of obstetrics lies in the avoidance of interference by those who have no right to molest the patient. The practitioner's best efforts are often thwarted by ignorant and meddlesome persons. He cannot, however, honestly forbid interference, unless he knows positively that there is no occasion to molest the patient. He will obtain the best results in obstetric practice who does the work himself, unless he can command, for certain things, the assistance of a trained nurse. Thoroughness in diagnosis, the faithful observance of antisepsis in treatment, and the protection of his patient from meddlesome interference, will give the best results. Such a method of procedure is thoroughly scientific, for it demands the best knowledge, the most careful and skilful manipulation, and, above all, an honest and fearless attempt to meet the difficulties that may arise. In the present stage of medical science, every woman has a right to demand such treatment, and if a practitioner of medicine cannot give his patient such care, he must inevitably, by the inexorable law of the "survival of the fittest," give place to those who can.

PREPUTIAL ADHESIONS IN CHILDREN, WITH CASES.

BY JOSEPH B. COOKE, M.D.,
ATTENDING PHYSICIAN TO THE NORTHWESTERN DISPENSARY, DEPARTMENT OF DISEASES OF CHILDREN; ASSISTANT ATTENDING PHYSICIAN TO THE OUT-DOOR DEPARTMENT OF ST. MARY'S FREE HOSPITAL FOR CHILDREN, NEW YORK CITY.

THE bearing of preputial adhesions in children on the causation of various reflex disturbances has been recognized and mentioned by writers for many years, but there seems to be a general tendency on the part of physicians to either greatly over-estimate the importance of the subject, or, more commonly, to lose sight of its significance entirely.

In December, 1892, I began a systematic examination of the genitals of all children coming under my observation with histories of disorders that might possibly be of reflex origin, including all of those indefinite symptoms so often ascribed to the presence of intestinal worms, together with every other morbid condition for which I did not at once see an adequate and evident cause.

The results of this investigation were not in the least degree startling; nor did I expect them to be so. Some of the cases examined had no adhesions whatever of the kind in question. Many of those that did present such adhesions were not benefited in any way by the removal of the condition; but, on the other hand, a sufficiently large number of children were so completely and so promptly relieved of their trouble that I am convinced that such an examination should never be neglected in any instance in which the prepuce might be thought to occasion reflex irritation.

The cases that have been selected as illustrations will serve to show the varieties of symptoms that may be due to the existence of preputial adhesions. I have not attempted to compile any statistical tables, but it may be safely said that *almost every child*, male or female, will be found to present some adhesions—possibly very slight ones—between the prepuce and the glans of the penis or of the clitoris, as the case may be. The time necessary to inspect the genitals and break up any adhesions that may be found is of so short duration that the comparatively small proportion of cures resulting from the procedure should deter no one from trying the experiment. Two or three minutes spent in this way *may* save a child many weeks of medication and discomfort, and its parents a considerable amount of anxiety and worry, to say nothing of the credit that will accrue to the physician if he be successful:

CASE I.—Priscilla ——, a colored child, eight and a quarter years of age, was seen at the Northwestern Dispensary, December 30, 1892. There was a history of pain in the right leg and groin for one day, causing her to limp. There had been incontinence of urine for two years, steadily growing worse. The urine was voided every hour by day, and often at night. The desire to urinate would arise suddenly, and without warning, and was sufficient to awaken the child from sleep. She never "wet the bed," in the ordinary acceptation of the phrase. She had exhibited choreic motions for two years, and was a "nervous" child, easily frightened. She often had "nightmare," and ground her teeth, and talked and moaned in her sleep every night. The prepuce was completely adherent to and entirely covered the glans clitoridis.[1] Retraction was attempted under cocaine on December 31st, but was given up on account of pain. Chloroform was administered,[1] and retraction was effected. No smegma was found between prepuce and glans. On January 1st the child's condition was unchanged. The prepuce was cleansed and dusted with iodoform. There was slight purulency of the denuded surfaces, due, probably, to a previously existing vaginitis.

On January 2d, the condition was yet unchanged.

On January 4th the child went to school. Urination was less frequent, and sleep was perfectly quiet. The child's father thought her general health better; he said that she was more lively, and less irritable.

On January 6th the child urinated less frequently, and with less distress than formerly. The pain in the leg and groin had entirely disappeared. The chorea had ceased entirely. There were no more "nightmare," and the like. Sleep was perfectly quiet.

This child has now been under my observation for nearly five months, and there has been no return of her symptoms. She has received no medicinal treatment of any sort.

CASE II.—Madge ——, a white child, ten years of age, was seen at the Northwestern Dispensary, on December 30, 1892. She gave a history of incontinence of urine for several years. The urine was not voided much oftener than normal, but micturition was sudden and without warning, occurring often in the street, and *sometimes* at night. She had "wet the bed" regularly up to four years of age, but seldom thereafter. She had presented choreic motions of increasing intensity for several years. She ground her teeth at night, and had "nightmare" constantly.

She had been treated for "worms" two years previously. No worms, however, appeared in the stools. For over a year and a half there had been pain in the leg and groin, mostly at night, interfering with rest. There was often merely a desire to stretch the leg. Asthma and dyspnea occurred on the slightest exertion for over two years. There was pain over the chest, stomach, and liver. The lungs and heart were normal. The child was slightly anemic, but its general condition was fair. The bowels moved once daily. There was slight edema of the lower eyelids that might have been due to anemia. The child had had measles, but the edema had been present previously. There was no history of scarlatina or of diphtheria. The prepuce was tightly adherent to and almost entirely covered the glans clitoridis. It was retracted under cocaine. There was no smegma. The surface was dusted with europhen. A teaspoonful of mistura rhei et sodæ, after meals, was prescribed. On January 2 the urine had a specific gravity of 1010, was of acid reaction, light-yellow color, clear, and contained no albumin. The prepuce was cleaned and dusted with iodoform.

The urinary symptoms were slightly worse, probably as a result of the additional irritation set up

[1] This condition is said to rarely occur in females of the negro race. Vide Morris, Amer. Journ. Obstet., Dec., 1892.

[1] General anesthesia was employed at the special request of the parents of the child. Vide the writer's article referring to this case, in THE MEDICAL NEWS, April 8, 1893.

by the freshly denuded surfaces of the prepuce and glans.

On January 4th the child was better as to sleep, pain in the leg, and urinary trouble.

On January 6th there had been no urinary trouble whatever since January 2d. The child was able to retain its urine, even when the desire to urinate had existed for some time. There had been no chorea or nightmare since January 1st, and no pain in the leg or groin since January 2d. There had been no dyspnea or asthma since January 2d, except on *severe* exertion. There was no more pain over the chest, stomach, or liver. The bowels moved twice daily. The rhubarb and soda mixture was withdrawn.

This child received no medication beyond the rhubarb and soda mixture mentioned. I have seen her at intervals of one or two weeks for several months. None of her troubles has reappeared.

CASE III.—James ——, a white child, seven years and ten months old, through his mother, applied for admission to St. Mary's Hospital, January 2, 1893. The mother believed the child to be ill with rheumatism. I visited his home to examine him for admission, and found him in bed. There was a history of severe pain in left foot, beginning a week before at about 5 P.M. The pain had extended up the leg to the hip by 9 P.M. of the same day, and was very severe during the night. The pain was intermittent and lancinating in character. There was no history or evidence of injury or local disease. On the following day the function of the leg was lost. The part could be moved only with great pain, and walking was impossible. On examination it was found that the pain was slight by day, provided the leg was not moved, but it became very severe by night, causing loss of sleep. The child cried out with pain during the night, and talked, moaned, and ground his teeth in sleep. He had been constipated several days ago, but the bowels were now regular. There had never been any urinary disorder. The leg had been wrapped in cotton-batting, and a turpentine liniment had been applied by the direction of a physician. The slightest manipulation caused great suffering. There were no signs of inflammation in any part of the leg. The pain was now chiefly confined to the left leg. The orifice of the prepuce was small, but the glans could be easily exposed. There was a *very slight* adhesion on the left side (the left leg was affected), near the frenum. This was readily broken up. All dressings (cotton-batting, etc.,) were removed from the leg, and no medicine was given. The child was not admitted to the hospital, but was told to get up and dress himself as soon as he felt so inclined. On January 4th the boy was up, and had no pain whatever. He could move the limb in every direction, and could walk, kick, and hop with the leg. On January 6th he was up and dressed. There was absolutely no pain or interference with the function of the leg. Six weeks later there had been no return of the symptoms.

Many more cases of this kind could easily be cited, but these are enough to emphasize the point in question. I have selected three instances, occurring within four days of each other, merely to show how little difficulty I met with in collecting data. None of these children had ever come under my notice before. As stated in the introduction to this paper, a large number of those children in whom adhesions were found were not benefited in any appreciable way by the removal of the condition, but no harm was done in breaking up the adhesions and placing the parts more nearly in their normal relations.

The technique of the procedure, if so important a term may be used, is too simple to require more than the briefest mention.

Boys with actual congenital phimosis should, of course, be circumcised, but in cases in which the orifice of the prepuce is of sufficient size to permit free exposure of half of the glans, the adhesions may, as a rule, be broken up by mere traction on the parts with the thumbs and fingers. If this is not enough, a blunt probe passed under the prepuce and swept around the glans, will complete the separation. Care must be taken to fully expose the corona, back of which considerable smegma will often be found. The frenum should also be carefully inspected, for, as shown in Case III, a very slight adhesion may be the cause of severe symptoms. The parts should then be thoroughly cleansed with warm boric-acid solution, dusted with some antiseptic powder, and anointed with vaselin or a bland ointment.

The penis should be inspected, and the prepuce fully retracted daily for three or four days, or until the mucous membrane has healed, in order to prevent the parts from growing together again. If the symptoms are actually due to the adhesions, they will probably be increased somewhat for the first day or two, owing to the additional irritation. If the symptoms return after two weeks or more, the parts should again be examined for fresh adhesions.

In girls the prepuce may be seized with a thumb forceps, and a probe will readily separate it from the glans clitoridis. The precautions and after-treatment already described are then to be carried out.

As a rule, the pain is very slight, and if an anesthetic is at at all needed, cocaine is all that is necessary. I do not think general anesthesia is to be recommended for so trifling a matter, as there is always an element of danger in its use.

The idea of carefully investigating this subject in children was suggested to me by the very interesting paper by Dr. Morris, in the *American Journal of Obstetrics*,[1] in which he describes the condition as it exists in young women.

341 WEST FIFTY-SIXTH STREET.

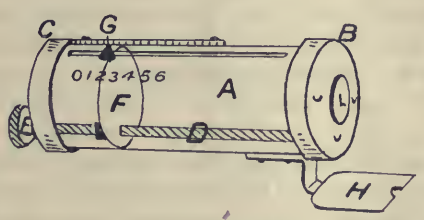
A NEW EYE-MODEL (ANAKLASIMETER[1]) FOR DETERMINING THE REFRACTION BY OPHTHALMOSCOPY AND RETINOSCOPY.

BY CARL WEILAND, M.D.,
CLINICAL ASSISTANT, EYE DEPARTMENT, JEFFERSON MEDICAL COLLEGE HOSPITAL, PHILADELPHIA.

THAT an *accurate* and *inexpensive* apparatus for practice with the refraction-ophthalmoscope is a desideratum will be conceded by all that have endeavored to avail themselves of this most valuable aid of ophthalmology. The tyro, especially, who has to learn the use of the ophthalmoscope and who must endeavor to relax his accommodation, is very much in need of an instrument that will allow him to accurately observe how far he has succeeded in his efforts; or, if he cannot relax his ciliary muscle wholly, how much accommodation he still employs in his observations.

It is for this reason that I have constructed a little model of the eye, which by axial changes permits the accurate determination of all refractive conditions from —10 to +10 dioptries, with or without astigmatism, in gradations of 0.50 dioptry, if wanted. The little apparatus consists essentially of a blackened tube, A (diagram), about one inch



Half of actual size.

in diameter and three and one-half inches in length, and closed at either extremity by metal discs, C and B, the anterior disk, B, having a central opening of about one-half inch, which contains a lens of +20 D power. Near the bottom of the instrument is a screw, D, which extends along the whole length of the tube and has at the back a little handle, E, which projects from the posterior disc and allows the screw to be turned. Along this screw there slides on a nut a plate, F, representing the retina, the position of which is indicated on the outside of the tube by a pointer, G. The number to which the pointer is directed indicates the refractive condition of the eye, the white numbers applying to the degree of hypermetropia and the red ones to the degree of myopia. From the anterior part of the tube projects a metal plate, H, which supports the ophthalmoscope and is so constructed that if the ophthalmoscope rests against it the lenses of the latter are exactly fifteen millimeters from the lens of the eye-model. In order to produce an astigmatic eye three little hooks are attached to the anterior plate, B, so that a —2 D cylinder can be slipped in and turned to any desired angle.

As, of course, the eye of the completely relaxed emmetropic observer is only adapted for parallel rays, it will only see the objects on the artificial retina distinctly if the rays coming from the eye-model have been made parallel by the lens of the ophthalmoscope. The numerical value of these lenses for the different positions of the retina can be easily calculated as follows: If f is the focal distance of the lens of the eye-model and d the distance of the artificial retina from this lens, then, by the known laws of refraction, b, or the distance of the image of the retina from this lens, will be determined by means of the formula: $\frac{1}{b}+\frac{1}{d}=\frac{1}{f}$; from which we find that $b=\frac{fd}{d-f}$. This equation shows that b is positive as long as d is greater than f, *i.e.*, the image of the retina falls in front of the lens, and we have therefore to do with myopia. The ophthalmoscopic lens is 15 mm. in front of the lens of the model, or b—15 mm. from the retinal image; it is therefore necessary to find a minus lens that has a focal distance of b—15 mm., so that the rays that would come to a focus b—15 mm. behind the ophthalmoscope are made parallel after their passage through this lens. The focal distance of this required lens must then be $b-15\text{ mm.}=\frac{fd}{d-f}-15$; or, in dioptries, its refractive power D must be $\frac{1000}{b-15}=\frac{1000}{\frac{fd}{d-f}-15}=\text{D}$.

From this we find that $d=\frac{(1000+15\text{ D})f}{1000-(f-15)\text{D}}$. This value for d shows us how far from the lens of the model we have to place our artificial retina in order to obtain a given number of (D) dioptries of myopia. In the same way we would find for hypermetropia that $d=\frac{(1000-15\text{ D})f}{1000+(f-15)\text{D}}$. (It must be remembered that the D's have to be taken with their absolute values only, without regard to the sign.) In this way the following two tables were found:

Myopia.

$d=50.00$	mm.	gives a	myopia	of	0. D.
$d=52.59$	"	"	"	"	1. D.
$d=55.37$	"	"	"	"	2. D.
$d=58.38$	"	"	"	"	3. D.
$d=61.62$	"	"	"	"	4. D, etc.

[1] From the Greek ἡ ἀνάκλασις, the refraction, and τὸ μέτρον, the measure. The usual word, *refractometer*, a compound of Latin and Greek stems, seems rather barbarous, and has therefore been avoided.

Hypermetropia.

d = 50.0 mm.	gives a	hypermetropia	of	0. D.
d = 47.5	"	"	"	1. D.
d = 45.3	"	"	"	2. D.
d = 43.2	"	"	"	3. D.
d = 41.2	"	"	"	4. D, etc.

In accordance with these two tables the scale of the instrument has been so constructed that all refractive conditions from —10 D to +10 D can be accurately determined. Practically all that is necessary is to take the model in one hand and the ophthalmoscope in the other hand, and then, after bringing the ophthalmoscope in contact with the rest, to find the highest plus or the lowest minus lens with which accurate and sharp definition of the details of the image can be obtained; and finally, to compare the number of the ophthalmoscope with that of the model. Perfect agreement shows perfect relaxation of the emmetropic eye; a plus lens in the ophthalmoscope too low or a minus lens too high by a certain number of dioptries shows just so many dioptries of accommodation used by the emmetropic observer. If the observer is not emmetropic, and if his refraction is not perfectly corrected, he has, of course, to make allowance for this in the reading of his ophthalmoscope.

If we place the cylinder of —2 D in its proper position in front of the +20 D lens we have then a sphero-cylindrical combination of +20 D in one and +18 D in the other main meridian. For the first meridian the former scale remains therefore the same, but for the +18 D lens a new scale is given below the other, so that the value of each meridian can be read off directly. Let, *e.g.*, the retina be at 85.7 mm. from the lens, then we find the pointer indicating a myopia of —7 D in one and of —4.5 D in the other.

How the instrument may also be used for retinoscopy will be clear from the foregoing description, and needs no further remarks. Of course, there are a good many contrivances that one might feel tempted to add, *e.g.*, a stand for the whole instrument, a changeable iris and a lens-holder in front of the rest for the ophthalmoscope, in order to get a point of reversal of 1 meter by using the lenses of the trial-case in this holder. The aim, however, has been simply to furnish a *reliable* and *inexpensive* means for the γνῶθι σεαυτὸν of the ophthalmologist and to omit all unnecessary accessories, which can be added, if desired. I am under great obligations to Mr. D. V. Brown, 740 Sansom Street, Philadelphia, for the elegance and accuracy with which the little apparatus has been constructed, and which is sold for $3.50.

IMPORTANCE OF ARTERIO-SCLEROSIS IN THE ETIOLOGY OF POSTERIOR SPINAL SCLEROSIS.

By GEORGE J. PRESTON, M.D.,
of Baltimore.

In studying the pathologic anatomy of posterior spinal sclerosis, one is struck by the fact that the lesion is practically confined to the dorsal and lumbar regions. In advanced cases the cervical cord is also involved, but this is probably in great part a secondary degenerative change. Cases of pure cervical tabes are certainly very rare, so rare indeed, as almost to put in doubt their existence as a part of tabes. So far as the histology of the spinal cord is concerned there is no reason why this should be so; the fiber-tracts increase rather than diminish from below upward, and *a priori* we would expect to find a larger area of sclerotic tissue in the cervical region than in the dorsal or lumbar.

In looking about for an explanation of this fact the first thing that strikes us is that the blood-supply of the three regions of the cord is derived from somewhat different sources. The cervical cord, the lower limit of which may be placed at the sixth cervical vertebra, is supplied with blood chiefly by means of the branches of the vertebral arteries. The vertebrals enter the spinal canal at the sixth cervical vertebra, and after giving off lateral spinal branches to the cord, send off two branches, which unite to form the anterior spinal artery, and two smaller posterior spinal branches. There are also a few small branches from the deep cervicals. These spinal arteries, viz., the anterior spinal and the two posterior spinals, run the whole length of the cord, forming a series of plexuses which supply both the cord and the vertebræ. The anterior spinal artery probably supplies the gray matter, while the posterior arteries, by means of the plexuses spoken of, are probably distributed to the white matter.

Below the level of the sixth cervical vertebra, or in the dorsal and lumbar portions of the cord, another very important set of vessels comes in, namely, the intercostal arteries. Each intercostal artery sends into the cord a spinal branch which enters more or less into the formation of the plexuses already spoken of. We have in the dorsal and lumbar regions of the cord a set of vessels not found in the cervical region. Moreover, these vessels are, probably, in the lower part of the cord, the most important source of the blood-supply, as the spinal arteries are, even at their origin small and tortuous, and in the lower regions of the cord very much reduced in size. The spinal branches of the intercostals probably enter the cord as peripheral branches supplying the fibers and not the gray matter.

The bearing of these anatomic facts upon the

pathology of tabes becomes very apparent when we observe the character of the intercostal arteries. The intercostal artery is a small vessel coming off virtually at right angles to the great trunk of the aorta. Now, as Thoma, Welch, and others have shown, it is in this type of vessel that we find the beginning evidences of arterio-sclerosis. The mouths of these small vessels at length become surrounded with a mass of calcareous material and the lumen of the vessel more or less occluded. It is quite possible to have these small vessels involved before there is any general manifestation of arterial change. This is seen in the case of the renal artery, an artery of the same type, that is, coming off nearly at right angles to the large trunk.

After this condition of sclerosis, or, in a higher degree, atheroma, has involved the intercostal arteries, a diminished amount of blood would be sent to the spinal cord, and, as a result of this imperfect supply of nutriment, there occur atrophy and degeneration of the nerve elements. As a consequence of this degeneration of nerve-matter there starts, partly from the sheath of the nerve, partly from the bloodvessel, an outgrowth of connective tissue, which, in its turn, encroaches upon the softer, less resistant nervous matter, giving us the characteristic picture of sclerosis. It has been noticed that the vessels are very generally thickened in tabes, Gowers especially calling attention to this fact, but not enough stress has been laid upon the outgrowth of connective tissue from the sheaths of the nerve-fibers.

In considering the etiologic factors that by common consent are conceded to be the most important in the causation of tabes, we find the first place given to syphilis; next in importance, perhaps, is exposure to cold and wet, which in most instances means rheumatism; and third, but not as prominent as we would expect, is alcoholism. Now, these are exactly the conditions most favorable to the development of arterio-sclerosis. Syphilitic inflammation of the arteries differs in many particulars from the rheumatic and alcoholic forms, but, so far as the destructive process goes, is just as important. Experience has taught us that we can expect little more improvement in syphilitic arteritis than in arteritis from other causes. In a few cases, perhaps, treatment is effective, but only in a small percentage of cases.

The ultimate distribution of the various sets of vessels to the cord is still so imperfectly known that it is impossible to say how far we are warranted in applying this same idea to degenerative changes in the other fiber-tracts, or even in the cellular elements of the cord. Sclerosis of nerve-tissue is such a general process, such a common form of degeneration, that one cause is by no means sufficient to explain all cases. The idea suggested in this paper is meant to include the majority of cases. Undoubtedly, traumatism, peripheral disease, specific poisons, and the like, are accountable for many cases, and the connection between these causative influences and the disease in question is often very close.

With this idea of the pathology of posterior spinal sclerosis I have been treating three or four cases under my own observation, and a number of other cases under the care of my resident physician, with nitroglycerin. The principle upon which this plan of treatment rests is that thus the small branches of the spinal arteries are dilated, and a larger supply of blood thus afforded the cord. Of course this can, theoretically even, only be done to a comparatively slight extent. It is rather too soon yet to speak of results, but almost all of the patients thus treated have improved, some of them notably. The element of mental suggestion was carefully eliminated, or rather was guarded against, as the patients were not told that they were taking any special treatment, and the inquiries concerning improvement were not unnecessarily frequent. The most marked improvement was noticed in the relief of pain. Two patients reported that they had begun to notice great improvement in walking. The dose of the drug in most of the cases was one one-hundredth of a grain, in tablet form, three times daily. Occasionally it happens that a patient cannot comfortably take this dose, and I have had to reduce one-half, which seems almost infinitesimal, but in these susceptible persons one two-hundredths of a grain will flush the face. On the other hand, much larger doses may be given. One of my patients took for some time a fiftieth of a grain t. i. d. This patient, however, was not a tabetic.

It is probably premature to publish these notes, but I am anxious to see if this remedy proves as successful in other hands as it has in mine. Another point that I would like observed is the condition of the mouths of the intercostal arteries in cases of tabes. This is such a chronic disease that one has often to wait a very long time to collect enough autopsy reports to warrant the drawing of inferences.

819 N. Charles Street.

Spontaneous Disappearance of Gonorrhea in the Course of an Intercurrent Acute Disease.—At a recent meeting of the French Dermatological Society, Bogdan (*Wiener medicin. Presse*, 1893, No. 21, p. 817) reported the case of a male, eighteen years old, under treatment for gonorrhea, in which the urethral discharge ceased a day after the development of an attack of left-sided pneumonia, to return with its previous activity during convalescence.

Barthelémy stated that he had observed two analogous cases in connection with enteric fever. Death occurred in one, without a return of the symptoms of gonorrhea. In the other an acute epididymitis developed on the seventeenth day.

CLINICAL MEMORANDUM.

EXTENSIVE FRACTURE OF THE SKULL FROM AN UNUSUAL CAUSE.

BY W. M. L. COPLIN, M.D.,
ONE OF THE VISITING SURGEONS TO ST. MARY'S HOSPITAL,
AND
O. D. SCHAUL, M.D.,
RESIDENT SURGEON TO ST. MARY'S HOSPITAL

H. M., twenty-five years old, a laborer, was brought to St. Mary's Hospital by the patrol wagon, on February 20, 1893. Accompanied by a friend, the patient had been carrying a keg of beer, when he slipped, and his head was caught between the keg and the pavement. When brought to the hospital he was conscious, but could not open his eyes on account of the swelling of the lids and an extravasation of blood into the loose cellular tissue of the upper eyelids. There was a steady oozing of blood from the nose and from the left ear; sub-conjunctival hemorrhage was also present.

Upon examination, the right side of the head seemed very much flattened anteriorly, the flattening including the right frontal eminence, the upper portion of the temporal bone, and the lower angle of the parietal. In contrast, the left side of the head, more particularly the external angular process, and in a line directly upward from the anterior angle of the frontal bone, projected forward and toward the left. There was no evidence of fracture upon the back portion of the head on either side, and no indication of contusion was noted at the time.

The patient talked rationally, and gave fairly sensible answers to all questions. There were no manifestations of motor lesions, no difficulty in coördination. The patient was not severely shocked, and did not show any pathognomonic symptom of cerebral injury.

Over the right frontal eminence was a small lacerated wound, which presented some of the characteristics of a punctured wound. It could not, however, be traced to the bone, and apparently extended only through the skin and superficial fascia. The patient vomited, the ejected matter looking like tobacco, with possibly some blood that had been acted upon by the gastric juice.

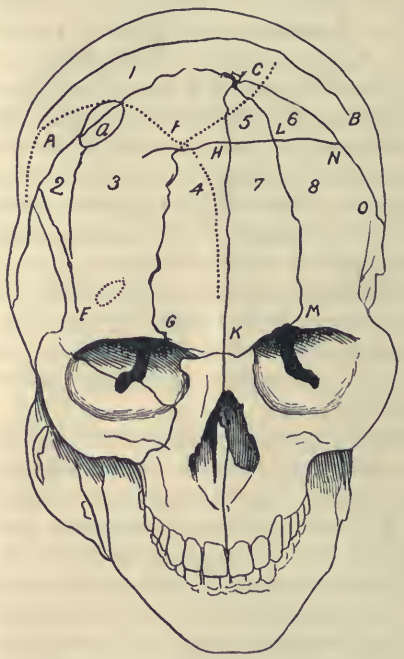
A line of fracture was found extending in the median line just above the forehead, and laterally down beneath the zygomatic arch. There were several areas over the depressed portion of the frontal bone, and one slightly back of the point of depression, that, to the finger, felt like wire under the tissues. These were, probably, the linear fractures to be described later on.

The head was shaved, and preparations made for an aseptic operation. An incision was carried over the median line of the anterior margin of the scalp, outward, backward, and outward over the apparent line of depression. All of the tissues were turned back, revealing a comminution of the anterior portion of the skull, as shown in the accompanying illustration. The trephine was inserted at the point shown in the illustration, and a small button of bone was removed. The rongeur forceps was then used to free the lines of fracture on either side, so as to permit of elevation. This was only partially successful. The fracture extending downward toward the base in the zygomatic fossa, and across to the orbital plate, could then be made out. From the anterior fossa several pieces of the base were removed. The accompanying illustrations show the lines of fracture.

There was no subdural clot, but there were several points of hemorrhage. Those in the dura were ligated, while those at the margin of the bone were arrested by plugging with threads of aseptic gauze. The latter procedure can easily be carried out by means of a needle, and is very efficient for the arrest of hemorrhage from vessels in bone. Quite a number of pieces of bone were removed from the orbital plate of the frontal bone, and a few that impinged on the cerebrum itself.

The dura was markedly lacerated at the base and in the temporal region. From all of these portions of laceration fragments of bone were removed. Little difficulty was found in arrresting the hemorrhage. A drainage-tube and some horsehair were passed down to the base, and carried out to the opening over the zygoma. The wound was then dressed.

FIG. 1.

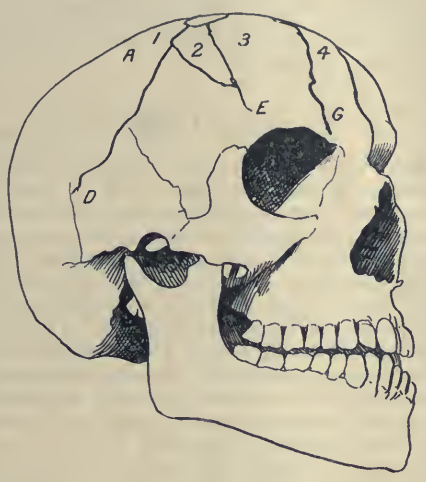


There were no evidences of fracture posteriorily, or on the opposite side of the skull, except the line that continued across, and as there was very little depression, and the patient was becoming considerably shocked, the wound was closed. Before it was closed, however, the finger passed under the dura showed that the points of depression were rather in the external plate than in the internal. The left ear was washed out with an antiseptic solution, and packed with mercuric-chlorid gauze. An attempt was made to treat the nose likewise, but was not fully successful, as the patient would not permit the packing to remain, and resisted every attempt at washing the nose out.

Immediately after the operation, which was completed at 2.30 A.M., on February 21, the patient was placed in a bed, and surrounded by hot bottles. At 3 A.M. he was resting comfortably, although he had not yet recovered from the ether. When consciousness returned he was restless and peevish, and readily annoyed. He com-

plained of being sore wherever he was touched, and repeatedly asked to be waked up. Even when he was answering questions intelligently he seemed to adhere to the fact that he was asleep. Immediately after the operation he was given gr. $\frac{1}{20}$ of strychnine, which was repeated three times during the day. He complained of moderate pain in the head. For the restlessness potassium bromid was offered, but refused. Once or twice during the day the man vomited. The vomited

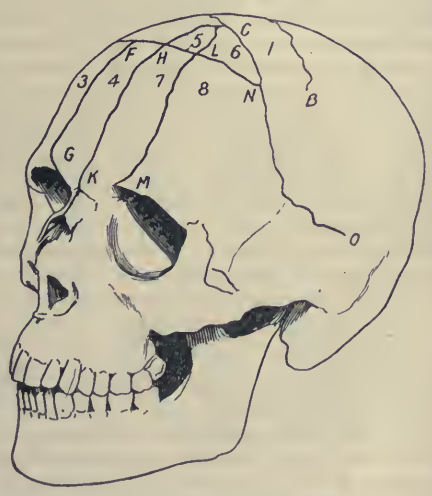
Fig. 2.



matter looked like tobacco-juice mixed with blood. The man could be induced to swallow but little nourishment—a little beef-tea and some milk.

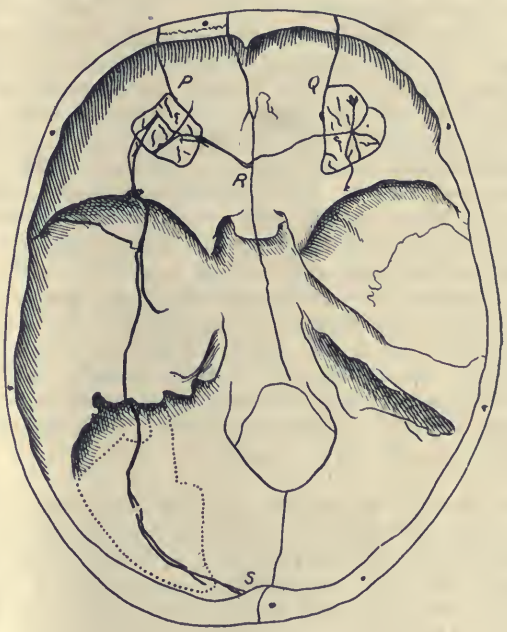
The wound was dressed on the morning of February 21, and showed no evidence of infection; there had been but little oozing. The oozing from the left ear continued; the hemorrhage from the nose had apparently

Fig. 3.



been arrested. There was intense ecchymosis around both orbits. In the afternoon, gr. $\frac{1}{8}$ of morphine sulphate was administered hypodermatically, after which the man enjoyed nearly four hours of quiet sleep. Whenever disturbed, he asked to be waked, and persisted that he was asleep. On the morning of February 22d, after a restless night, uneventful in any particular, the wound was dressed. There was no evidence of suppuration; the gauze was pretty freely saturated with serous oozing, and the flow from the left ear had been free and continuous. The patient was not fully conscious, but answered many questions intelligently. He seemed easily worried, and became annoyed by the slightest disturbance. He expressed a desire to know the day of the week, and regretted that he had not been able to vote. He also expressed a desire to go home, and told his mother that he would "be up right away." He continued to believe that he was asleep, and would not permit his eyes to be opened, as he believed that the opening of the lids would lead to blindness. He complained slightly of fulness and pain in the head. He made several attempts to rise from bed, and expressed a desire to go home, stating that if those about him did not stop resisting his movements he would "holler murder." He was restless, and rolled uneasily from side to side, and made numerous attempts to remove the bandage from his head.

Fig 4.



On February 23d the symptoms had not materially altered; the man still answered questions rationally, his delirium partaking of the desire to be waked up. His pulse was fairly good. He complained of pain and aching all over, without being able to definitely locate any point of pain of greater intensity. He was restless, and occasionally rose up suddenly, and asked to be awakened, and wanted to go home. The wound was dressed, and looked perfectly healthy.

On February 24th the restlessness was somewhat increased. The man persisted in strongly blowing his nose, and constantly wanted to go to the water-closet. His extremities were cold, and his pulse seemed weaker than on previous days. He was given one-thirtieth of a

grain of strychnine three times during the day. In the afternoon the restlessness increased, and attempts were made to retain an ice-bag on his head. The temperature rose to 102° F. The wound looked well; the drainage had been removed; there was some discharge from the left ear, although it had been suppressed on the day before. At 9 o'clock in the evening the pulse rose to 136; it was weak, later became fuller and slower, and reached about 100. At 10 o'clock he began to sink gradually; unconsciousness became more profound; there was picking at the bed-clothes, tremor of the hands and legs, and general cyanosis; restlessness ceased with the development of coma, and death occurred at 1 o'clock on the following morning, without any material alteration in the symptoms, except a progressive increase in severity.

On the first day the temperature rose from 98° F. to 100.6° F.; on the following morning it was 98.2° F., on the evening of the second day 99.4° F., on the morning of the third day 99° F., in the evening 99.2° F.; on the morning of the fourth day the temperature had dropped 4° F., to 98.8 F.; in the evening it was 99° F.; on the morning of the fifth day the temperature was 99.2° F., but by evening it had risen to 102.6° F., and at the time of death, on the morning of the sixth, the temperature had fallen two degrees.

The post-mortem examination was made six hours after death. The accompanying illustrations show the extent of the fractures. A large clot was present in the posterior fossa, between the dura and the skull, from the line of fracture on the left side. The right tempero-sphenoidal lobe was lacerated in an area one and one-half inches long, one inch wide, and one inch deep. At the lower portion of the left inferior frontal convolution the brain was lacerated in an area one and one-half inches long, one inch wide, and one inch deep. A little above the laceration, in the tempero-sphenoidal lobe, was a large vein, about the size of a goose-quill, occluded by a thrombus. All of the vessels of the pia mater and arachnoid were distended. A slight fibrinous exudate covered the convolutions in different areas, but was not universally disseminated upon the brain. Examination of the trunk was not permitted.

Remarks.—An examination of the illustrations and the post-mortem notes will indicate the extensive character of the injury sustained, and, at the same time, the small number of the cerebral symptoms that were present. It is probable that when vital centers are not involved the brain is competent to withstand most extensive traumatisms, and when asepsis is secured there is reason to believe that recovery will take place in a large percentage of cases. From the second to the fifth day after the accident there were no symptoms attributable to any grave lesion or inflammatory process within the cranium. This is well shown by the temperature curve, and is probably to be explained by the avoidance of infection. On the fourth or fifth day, by reason of defective asepsis, infection took place through the nasal cavity. It is probable that the Eustachian tube is always infected, and when the fracture passes, as this did, through the middle ear, it affords a seat for infective processes even better than does the passage of infective matter up through the fissured ethmoid. It is probable also that packing of the nasal cavities will more efficiently prevent infection through the superior nasal orifices than through the Eustachian tube. In a similar case we would be tempted to plug the posterior nares thoroughly, and treat the nose as a closed cavity, applying antiseptic solutions freely. We do not think that asepsis can be secured in the nasal cavities by washing out and packing, without at the same time plugging the posterior nares. While it is probable that the elevation of temperature is to be ascribed to infection, it is not impossible that this may have been due to the process of repair and an exudation of serum; but the lateness of the rise rather indicates that infection occurred, and to this death is to be attributed.

Explanation of Illustrations.

A B, linear fracture, posterior to the coronal suture at A, slightly anterior to the coronal suture at B. C, point of union directly over the longitudinal sinus. Q, on the interior of the skull, marks the point where the linear fracture, F G, continues through the orbital plate, and terminates in the comminuted mass in the orbital plate of the frontal bone. It will be seen that the two comminuted areas, P and Q, communicate with each other through the linear fracture that crosses the median line at R, and is there continuous with the linear fracture, C H K, on the external surface, the line of fracture stopping at R. From the comminuted area P we have a linear fracture extending backward through the semicircular canals, possibly involving the cochlea, and terminating at S, slightly above the torcular Herophili.

It will thus be seen that every bone in the cranium was fractured, and all in most unfavorable situations, except the right temporal bone, which only had the upper angle of the squamous portion fractured to an extent of about one inch.

a marks the area from which the trephine button was removed. 1 is intended to label the area that might be called a fragment, except that it is not detached at either end of the linear fracture A B. Fragment 2 was removed. The irregular-shaped fragment 3 was depressed at its superior angle, and caught by fragment 1. In order to be able to raise 3, the rongeur forceps was used in making a line from the trephine point to F, and then the upper fragment of 3 could easily be raised; the lower fragment was raised with more difficulty, and less successfully. Fragment 4 was raised. Fragment 5 was also raised. Fragment 6 did not seem to be depressed. Fragment 7 and 8 could not be readily raised. Through the opening made by the rongeur forceps and the removal of fragment 2, many pieces were removed from the comminuted mass situated on the right orbital plate of the frontal bone. The oval dotted line above E marks the point of the punctured wound in the scalp, already referred to, there being no injury to the skull proper at that point. The dotted line just above K marks the site of the skin-flap first made. It was afterward found necessary to make a branch cut-off from F, in order to expose fragments 5, 6, 7, and 8. A drainage-tube was brought out below A, having its exit through the skull, where fragment 2 had been situated. The dotted lines in the posterior fossa mark the area in which a subdural clot was found after death.

The method by which these lines were obtained is, so far as known, original with Dr. Coplin. The skull photographed in the drawing is a French preparation, having the internal ear dissected out, and is easily separated into pieces. It was coated over with mucilage and, while moist, black silk was used to mark the lines of fracture. This was done by the resident physicians following the lines discovered at the post-mortem. The result was then photographed, and reproduced as shown. If No. 8 black silk is used, beautiful lines can be made by this method. The vertical section of the skull occupies the line shown in the linear fracture at K, which, in the case reported, terminated at the articulation with the nasal bone, extending from this backward, as shown in the interior of the skull as far as R.

MEDICAL PROGRESS.

Operative Removal of an Enlarged and Displaced Spleen.—At a recent meeting of the New York Surgical Society, MARKOE (*Annals of Surgery*, vol. xvii, No. 5, p. 582) presented a woman, aged sixty-four years, from whom he had, seven months previously, removed an enlarged and displaced spleen. Several years before, the woman had strained herself in attempting to lift a sick child from a crib with fixed and high sides. Pain was felt low down on the right side of the abdomen, where there was also noticed a protrusion, the reduction of which was followed by relief. On the following morning the woman was seized with faintness, nausea, and trembling, although she had fainted before. From this time excessive muscular exertion or unusual position was attended with displacement of the lump and discomfort. Some time later, after a fall down stairs, the lump increased in size, and there was additional discomfort. Now there began to be increased frequency of micturition, aggravated by activity, by standing, and by walking. A feeling of pressure in the rectum was experienced, which was especially distressing when constipation existed. Digestion was greatly deranged. On one occasion the woman was seized with a severe attack of colic lasting for more than an hour and attended with marked bearing-down pains. The tumor was believed to be splenic, but there was no evidence of malaria or leukemia. After a period of restorative treatment preparatory to operation, a long incision was made in the median line, and the enlarged organ was dislodged from the pelvis and lifted into the wound. The inferior extremity lay tightly wedged in the pelvis, the anterior surface looking anteriorly and inferiorly, while the hilum was behind and somewhat above. The stomach had been dragged down with the spleen, and the gastro-splenic and suspensory ligaments were stretched into a broad, thin pedicle, in which several accessory spleniculæ were seen, in addition to the large and tortuous vessels. The greatest care was exercised to avoid undue tension upon the pedicle. The splenic artery was isolated and tied with a stout silk ligature. The pedicle was then doubly transfixed and tied with three locked ligatures, the inferior of which was tightened first. The portion included in this ligature was then cut away from the spleen, but immediately retracted, the ligature becoming detached, and a momentary sharp venous hemorrhage resulting, which was, however, immediately and efficiently controlled by the application of a large clamp. The remaining portion of the pedicle was grasped with two similar clamps and the spleen was cut away. The two remaining ligatures were then tightened and the clamps cautiously removed. To guard still further against slipping, the pedicle was additionally transfixed at its center and all was included in a ligature of strong silk. An accessory spleen as large as an egg was treated in the same manner, several smaller ones being left behind. The wound was closed without irrigation or drainage. The operation occupied an hour and forty minutes. Reaction was perfect. The urine first passed after the operation contained a large number of leukocytes, but was otherwise normal; two days later it was absolutely so. Examination disclosed no change in the number or relation of the blood-cells. A month after the operation the woman was permitted to return to her home, though cautioned to wear an abdominal bandage and to rest for another month. She grew steadily stronger and better, and was entirely relieved of all symptoms. The spleen weighed a little over five pounds and a half, the accessory spleen half an ounce. Microscopic examination of sections of the organ disclosed no pathologic change beyond some relative increase in the amount of connective tissue.

Tumor of the Pituitary Body.—WADDELL (*Lancet*, No. 3634, p. 921) has reported the case of a man, thirty-nine years old, who for two years had observed progressive impairment of vision, which was found to be due to partial bi-temporal hemianopsia. Both eyes were rather prominent; the pupils were equal and reactive to light; neither fundus presented any characteristic abnormality; the functions of the external ocular muscles were preserved. A diagnosis of tumor of the pituitary body was arrived at, although there was no history of syphilitic infection and no indication of akromegaly. In the past there had been but occasional headache. The reflexes were unaltered. The first indication of serious activity of the supposed tumor was the occurrence of intense frontal headache, with great prostration and a rapid short pulse. The axillary temperature was 103°; the tongue was heavily coated; there were nausea and vomiting; the face was flushed, the eyes full and injected; the patient was drowsy, but unable to sleep. These acute symptoms gradually subsided in the course of two or three days. Subsequently, slight attacks of frontal pain occurred at intervals, and the man was only with difficulty roused to any activity. He would remain for a long time in a quiet, absent-minded condition, from which he would occasionally start and ask some unimportant question, which he would repeat a short time afterward. He could clearly recall events that had occurred many years before, but not recent events. Later on, the right pupil became dilated and reacted to light, but imperfectly. The reflexes became diminished. The urine presented no abnormality. The frontal headache, previously variable, now recurred periodically about every two weeks. These exacerbations were always preceded by more than usual depression of mind, which was followed in a few hours by quickening of the pulse, a steady rise of temperature, and increasing frontal pain. The face and eyes were invariably suffused, and the bodily prostration and drowsiness were intense. The paroxysms generally lasted from twenty-four to thirty-six hours, and gradually subsided, each succeeding one leaving the man weaker than before. In one of these attacks right hemiplegia appeared, with partial loss of consciousness, increased frequency of pulse, elevation of temperature, double strabismus, and dilatation of the left pupil (as well as of the right). Consciousness began to return in a few hours, the temperature and the frequency of the pulse diminishing; the paralysis gradually passed off, and in twenty-four hours no trace of it was left. Total aphasia existed for about thirty-six hours after the return of consciousness. The patient, however, never entirely rallied, and recurring attacks of pain in the head, defective assimilation, and the formation of bedsores brought about a fatal termination from asthenia. When the skull-cap was removed the brain presented a somewhat

shrunken appearance. On removing the brain a firm, consistent, reddish-brown, oblong tumor, an inch long and less than three-quarters of an inch wide, involving the anterior lobe of the pituitary body, was found. Lying immediately to the left was a collection of fluid venous blood, retained in the form of a clot by a fold of membrane. The tumor pressed about equally on the two optic nerves.

For the Formation of an Artificial Sphincter after Extirpation of the Rectum, WILLEMS (*Centralbl. für Chirurgie*, 1893, No. 19, p. 401) recommends the following procedure: After the lower segment of the rectum, with the sphincter ani, has been removed through a perineal incision the patient is placed in the lithotomy position. If a large portion of bowel has not been removed the distal portion can be readily reached and drawn down. An oblique incision is now made over the tuber ischii, about two inches long, and extending upward and outward, in the course of the fibers of the gluteus maximus muscle. The muscle-bundles are separated with a blunt instrument, about a half-inch from the lower margin of the muscle. The bowel is drawn through this opening and attached to the external skin. If a large portion of the rectum has been removed, the sphincter must be established higher up. The patient is placed in the lateral position and an incision is made through skin, connective tissue, and aponeurosis, extending from the uninjured, right margin of the sternum downward and outward. The muscle is separated in the manner already described (the tuberoso-sacral and the spinoso-sacral ligaments will also have to be divided), and the bowel is attached to the skin. After the artificial anus has been established the wound can be drained and packed.

THERAPEUTIC NOTES.

The Treatment of Suppurating Buboes.—OTIS (*Journal of Cutaneous and Genito-urinary Diseases*, vol. xi, No. 128, p. 174) reports the treatment of 16 cases of suppurating bubo by means of injections of a mixture of iodoform and vaselin. Of this number, 9 were cured in six days, 3 in twelve days, 1 in fourteen days, 1 in twenty-three days, and 2 failed to report. The skin for some eight or ten inches about the affected area having been rendered thoroughly aseptic by scrubbing with green soap, washing with sulphuric ether, and douching with a 1 : 1000 solution of mercuric chlorid, a narrow bistoury was introduced into the abscess-cavity, and the contents gently, yet thoroughly expressed. The cavity was irrigated with a 1 : 1000 solution of mercuric chlorid, and immediately filled, by means of an ordinary cone-pointed glass syringe, to moderate distention with warm iodoform-ointment, the degree of heat not being sufficient to liberate free iodin. The plunger of the syringe being removed, the barrel was gently heated in the flame of an alcohol-lamp, filled with the ointment by means of a spatula, and the plunger replaced. On finishing the injection and withdrawing the syringe, a cold compress wet with cold mercuric chlorid solution was applied. The ointment was at once solidified at the orifice of the cavity, so that the contents could not escape. A large compress of dry mercurial gauze was applied, covered with a protective dressing of cotton, and retained by means of a firm spica. If at the end of four days all had gone well the dressing was reapplied, but if there was any evidence of inflammatory action the wound was thoroughly irrigated and cleansed, and the injection repeated.

The Epidermatic Employment of Guaiacol.—SCIOLLA (*Rif. Med.*, No. 7; *Wiener med. Pr.*, No. 19) has found that topical applications of guaiacol to the skin have the property of reducing high temperatures, not only in cases of pulmonary tuberculosis, but also in other febrile conditions. The influence is observed soon after the application has been made, and is the more energetic if the surface treated be covered with some impermeable material. Fifteen minutes after the application the characteristic taste of guaiacol can be perceived; then the temperature begins to fall, and more or less profuse perspiration takes place. The temperature frequently falls to the normal in the course of a few hours. There are no unpleasant complications, such as cyanosis, coma, and the like; on the contrary, the antithermic effect is attended with agreeable subjective sensations. Guaiacol thus applied to the skin is excreted by the kidneys as guaiacol-ether sulphate, which first makes its appearance in about an hour after its application and reaches its maximum elimination in five or six hours. The application may be made several times daily. The largest amount used in twenty-four hours was a little less than an ounce. A similar line of observations with creasote had to be abandoned on account of the caustic effect of the applications.

Menthol for Pruriginous Conditions.—COLOMBINI (*Giorn. Ital. d. Mal. Vener.; Wiener med. Pr.*, No. 19) has obtained excellent results from the employment of preparations of menthol (from 5 to 10 per cent. in alcohol, from 1 to 6 per cent. in oil, from 2 to 6 per cent. in powder) in the treatment of pruritus from whatever cause, but especially in those cases in which the scratching of the skin was responsible for the cutaneous affection, and particularly in cases of urticaria, in some forms of eczema, and in the pruritus of scabies. Preparations applied to excoriated surfaces or to mucous membranes should not be too concentrated, else they will cause burning; nor should too extensive surfaces be treated at once, as the sensation of cold produced may become disagreeable. In cases in which the itching is but a symptom, the primary disease will require special treatment. In such cases menthol can only bring about amelioration, and the pruritus will not entirely disappear until the causative disease has been cured.

The Treatment of Acute Nephritis with Methylene-blue.—Governed by the view that acute nephritis is of microbic origin, and by the knowledge that methylene-blue will inhibit bacterial development, NETSCHAJEFF (*Berliner klin. Wochenschr.*, 1883, No. 20, p. 470) employed this drug in the treatment of fifteen cases of acute nephritis, with excellent results. Tablets of a grain and a half were given thrice daily on alternate days. The urine was discolored in the course of an hour, and on the following day its volume was augmented. Albumin and tube-casts gradually disappeared. There were no unpleasant secondary manifestations.

MENINGITIS SEROSA.

MOST practising physicians have experienced the great difficulty in cases of meningitis of deciding as to the precise nature of the disease, and more particularly as to the exact character of the effusion. The serous form of meningitis has been so well discussed in a recent paper by H. QUINCKE, of Kiel ("Ueber Meningitis Serosa," *Sammlung klinische Vorträge*, March, 1893, N. F., No. 67), that we have deemed it worth while to present a brief summary of this, together with some general remarks upon the differential diagnosis of the different varieties of meningeal exudation.

QUINCKE distinguishes serous meningitis from hydrocephalus on the one hand, and purulent inflammation of the meninges on the other hand. He believes that the watery effusions into the meninges and into the ventricles are of inflammatory origin, and describes some fourteen cases that have come under his notice. The cases are divided into (*a*) those beginning acutely and (*b*) those beginning slowly; the former being further subdivided into (1) those running an acute course and (2) those that pursue a chronic course. The chronic cases in turn are subdivided into (1) those of a progressive course and (2) those that are attended with acute exacerbations.

It has long been known that in diseases within the skull more than in those in any other situation in the body, it is the extent of the disease-process rather than its anatomic character that is of significance as to the severity and course of the affection. This holds good for tumors as well as for collections of pus and blood, and in a more striking way for the relatively indifferent serous fluids within the cranial cavity, which, though situated in most indifferent regions and without the production of focal symptoms, may cause death. The actual size, however, of an exudate that may lead to a fatal termination is subject to individual variations. As the actual harm done is due to the pressure of the fluid on the brain-substance, in every case three factors necessarily come into consideration: (1) the amount of the exudate, (2) the rapidity with which it is poured out, and (3) the relation of the size of the brain to that of the containing cranium.

Thus it is often difficult at the post-mortem examination to judge of the pathologic significance of watery exudates within the skull, whether in the ventricles or in the sub arachnoid species. Of course, edema of the brain-substance is always a pathologic condition. The amount of fluid found in the cavities, even in health, represents only the space within the skull not occupied by brain-substance; and in old age, in the diffuse or partial atrophies of the brain, and under various other conditions, the amount of cerebro-spinal fluid may be considerably increased without any evidence of abnormal intracranial pressure.[1]

Very often, at autopsy, a fresh exudate can be distinguished from such a *hydrops ex vacuo* only by the tension of the membranes and the flattening of the convolutions; but after death, even in cases in which pressure-symptoms during life have been marked, it is not always easy to make out these signs, as the *turgor* may, like serous exudations in other parts of the body, disappear after death. Again, primary exudates within the ventricles, which have come on slowly and have lasted a long time, may cause few symptoms pointing to an increase in pressure, as the brain-substance adapts itself to new relations more readily than might be supposed.

These are among the difficulties that have made

[1] Numerous observers have tried to lay down a standard of intra-cranial pressure to be regarded as normal; thus, Bischoff places it at between 41 and 103 g., while Quincke says that any pressure over 50 g. is to be regarded as pathologic.

the whole subject of hydrocephalus so obscure, and although we are able to enumerate the different modes of origin of hydrocephalus, and perhaps to explain the general pathology of the affection, yet it is still impossible to make a classification that will suit all cases.

The number of cases in the literature that can fairly be regarded as instances of serous meningitis is comparatively small, though the examples of BAGINSKI and STEFFEN of meningitis ventricularis, the acute lepto-meningitis in children of HUGUENIN, and the serous meningitis of EICHHORST may properly be classed under this heading. OPPENHEIM, PLEHN, and SOCIN have also recorded cases. It is probable that the disease is not nearly so infrequent as the literature would lead us to suppose, as in many cases in which there has been no autopsy there is little doubt but that acute serous meningitis has often been diagnosticated as purulent meningitis, and the chronic forms of the affection have been added to the list of brain-tumors. Even when autopsies are made, insufficient attention is frequently paid to the amount of exudate present.

The clinical picture of the acute form varies considerably. The disease may be as sudden in onset as purulent meningitis, but it is generally slower in course and simulates rather tuberculous meningitis. QUINCKE emphasizes the absence of fever, and says that when this is present it is only slight in degree, does not last long, and shows many irregularities in its course. Pain in the head and retraction of the neck are usually present, but vary in intensity, and are not such prominent symptoms as in the purulent or tuberculous forms. Mental disturbances appear later, and are less marked than in meningitis purulenta. If they continue long they render the prognosis grave. Delirium, sleeplessness, hyperesthesia, pain in the joints, and local paralyses may occur. Spasms in extensive muscle-areas, often epileptiform in character, are not infrequent. Vomiting occurs often; the pulse may be slow and irregular; the pupils are frequently unequal, but, as a rule, present no marked changes. Choked disc seems to be very frequently demonstrable, and QUINCKE holds that this sign is almost constant. In cases of recovery it may disappear, but occasionally it leads to atrophy and amblyopia. The irregularity of the symptoms is often more marked than in the ordinary forms of meningitis, and the clinical picture varies greatly from day to day, or even from hour to hour.

In the more insidious cases, and in those that run a chronic course, sometimes continuously progressive, sometimes with intermissions and exacerbations, the symptoms resemble very closely indeed those of brain-tumor.

The disease is chiefly one of children and of young adults, and, as a general rule, the younger the patient the greater the tendency to chronicity, with acute exacerbations. Injuries to the head, excessive mental effort, acute and chronic alcoholism, and the acute febrile diseases have been mentioned as the main causes. In chronic cases pregnancy is often responsible for exacerbations. According to QUINCKE, bacterial infection does not play a part in the etiology of serous meningitis.

To understand clearly the pathology and pathogenesis of meningeal affections, it is necessary to recall some of the facts of the physiology of the central nervous system and its meninges. It will be remembered that, normally, the cerebro-spinal fluid in the ventricles, as well as in the sub-arachnoid spaces of the brain and cord, is a secretion that flows off, mixing with the lymph through the arachnoidal villi (Pacchionian bodies), and through the tissue-network at the points of exit of the nerves. The experiments that have been made with cinnabar show that resorption is greater in the meninges of the brain than in those of the cord, and these, along with the experiments of FALKENHEIM and NAUNYN, have proved that absorption takes place chiefly by means of the Pacchionian bodies. Normally, of course, there must be a certain definite relation between the amount of secretion and the rate of absorption, and between the secretion into the ventricles and that which is poured out in the sub-arachnoid spaces. Excluding *hydrops ex vacuo*, which we have already mentioned, the general conditions that give rise to a pathologic increase in the amount of cerebro-spinal fluid are much like those that account for the accumulation of fluid in the pleural or peritoneal cavities, that is to say, lymphstasis, blood-stasis, and inflammation.

QUINCKE distinguishes meningitis corticalis sharply from meningitis ventricularis, and says that in the former the fluid has a tendency to be turbid and the disease to be parasitic in origin, while in the latter the fluid is clear and the disease is very rarely due to infection. He compares the intra-ventricular form with intermittent joint-effusions, with urticaria, and especially with acute angio-neurotic edema. He thinks that the affection is more com-

mon in children, because in them the vascular walls are much more likely to undergo changes that render them permeable, and also because an exudate into the brain of a child is more frequently followed by serious symptoms, as it offers less resistance than that of an adult.

In many cases of serous meningitis cure is effected through cessation of the exudation or through a compensatory process, partial or complete, by means of which the efferent channels are widened. Even when a high degree of pressure has lasted for a long time and has led to continuous dilatation of the ventricles, there may yet at a later time be a return to the normal pressure; and in children the dilatation of the ventricles may disappear with increasing years. In those cases in which the compensation is incomplete, even though only apparently trivial symptoms remain, there is always danger of sudden death from an acute exacerbation.

The diagnosis is perhaps that which interests the practical physician most. The acute form is likely to be mistaken for purulent meningitis, but the absence of fever or the presence of but a slight degree of fever, the slower course, the more variable symptomatology and the choked disc in the former, as a rule, enable us to make the distinction. The more subacute forms resemble closely tuberculous meningitis. Both diseases are insidious in onset and often remittent, but the absence of tuberculous disease in other organs, the normal temperature, and the general course are in favor of meningitis serosa. It is to be remembered, however, that in individuals with tuberculosis there may be a complicating serous meningitis. The diagnosis of chronic cases is still more difficult. These can be distinguished from brain-tumor only rarely *intra vitam*. Serous meningitis may give rise to focal symptoms, paralyses, convulsions, and localized pains in the head. Choked disc and blindness appear more quickly, however, than in brain-tumor. Most puzzling are those tumors of the posterior fossa of the skull that give rise to hydrocephalus from stasis. QUINCKE regards as important the application of a test that he designates lumbar puncture, in conjunction with examination of the fluid obtained. A specific gravity of 1009 with an amount of albumin of over two parts per 1000 is suggestive of hydrocephalus through blood-stasis. To distinguish the auto-intoxications (*e. g.*, acetonemia) from instances of the acute form, one will be guided by careful examination of the eyes and of the urine, and by lumbar puncture. In the very chronic and very mild cases serous meningitis may present symptoms of cerebral neurasthenia, and one cannot be positive whether he is dealing with an organic affection of the nervous system or not.

As to treatment, in the acute form anti-phlogistic measures are recommended; the application of leeches to the neck, the ice-bag, the use of intestinal derivatives, complete rest, and avoidance of excitement are advised. QUINCKE lauds highly the administration of mercurial preparations, preferably by inunction, or, if a speedy effect be desired, by hypodermatic injection. He keeps up the treatment for from four to six weeks, and has found it to be of great service in many cases. He suggests the use of pilocarpine, but has not tried it, and states that, as in other angio-neuroses, something may be expected of quinine and antipyrin during slight exacerbations. In the more chronic cases he uses flying vesicants on the skin of the head and neck, painting with iodin, and, most of all, cautious inunction with an ointment containing tartar emetic. When imminent danger is to be apprehended from the intra-cranial pressure, he would resort to lumbar puncture, removing from 5 to 80 c.c. of fluid through a hollow needle introduced at a distance of one centimeter from the middle line beneath the second, third, or fourth lumbar vertebra.

EDITORIAL COMMENTS.

Changes in the Medical Department of the Army.—Surgeon-General Sternberg, the new chief of the Medical Department of the Army, contemplates two important changes for the benefit of that service. One is the establishment of a special course of training for newly-appointed officers of the corps. This course will be given in Washington, and will constitute what will be known as the Army Medical School. It will be conducted in the Army Medical Museum and will be of four months' duration. Four of the senior medical officers stationed in the city will, in addition to their other duties, conduct this course.

The other project of General Sternberg is to give the officers of the medical corps the advantages accruing from metropolitan life. He proposes to change the system of assigning medical officers for duty as attending surgeons in the large cities. It has been the custom heretofore to detail for this purpose the older medical officers of the army. The duty usually lasts three or four years. In some cases it has lasted ten or a dozen years. The duty of the officer so detailed is to attend army officers and their families in and about the city of his location. Dr. Sternberg will hereafter detail medical officers having the rank of captain to duty as attending surgeons. The tour of duty will last only one year. By

this system the medical officer selected will be enabled to become familiar with the practice of the leading physicians and surgeons in this country and to attend medical lectures and meetings of medical societies. The experience and observation will fit them the better for their second examination, which is required by law before they can be promoted to majorities.

The Antiseptic Virtue of Iodoform.—Iodoform holds a unique position in its relation to antiseptic surgery. Although it has been demonstrated that the drug possesses no direct germicidal property, there is a general consensus of opinion that used in one form or another, as a powder, in emulsion, by inunction, it exerts an influence that may be considered antiseptic. An adequate explanation of this action is wanting, abundantly confirmed by observation though it is. In his recent address upon "The Antiseptic Management of Wounds," SIR JOSEPH LISTER adopts the view that iodoform acts by inducing chemical changes in the toxic products of bacterial activity, a plausible explanation, inasmuch as we know that the constitutional manifestations of infective processes in general are not so much dependent upon the mere presence of microörganisms as upon the development of toxins. TREVES (*Lancet*, No. 3641, p. 1375) offers a contribution to this interesting subject, in which he reports the generous application of iodoform in powder within the peritoneal cavity in the course of abdominal operations, with results that appear not entirely unrelated to the use of the drug. The special utility of iodoform applied to tuberculous tissues is well known. In our appreciation of the utility of iodoform we must, however, not ignore its toxicity, but should always exercise the greatest care in its employment.

Cholera in France.—There is, unfortunately, good ground for believing that the public is being deceived by the suppression of news as to the existence of cholera in France. It is sufficiently alarming to learn that about a thousand deaths occurred from the cholera in Mecca in one day last week. But when we are assured that the disease has travelled so far west as France, and that in one week 562 cases, with 178 deaths, occcurred in Lorient, France, it is certainly time that immigration from France should be restricted, or scrutinized with profoundest care. A sailor on a ship from Nantes, France, died of cholera at Newcastle, England, some two weeks ago, and deaths have occurred at Malta under similar circumstances The epidemic has also appeared in Catalonia, Spain. The warning is all the more needed because all information as to the condition of the West Coast and the general spread of the disease throughout France is being rigidly suppressed. This mistaken policy arouses rather than quiets apprehension in the minds of the prudent.

Pernicious Anemia and Chlorosis in the Negro.—There is no evident reason why individuals of African descent should be less susceptible than members of the Caucasian race to the diseases characterized by qualitative and quantitative changes in the constitution of the blood; but on account of the absence in dark-skinned people of the pallor of the integument usually attendant upon these conditions, and the lack of other distinctive symptoms, the blood-examination is less commonly made in colored than in white persons. It is on this account, perhaps, that reports of cases of anemia in negroes are uncommon. Musser (*University Medical Magazine*, July, 1893, p. 770) records a case of pernicious anemia and one of chlorosis in colored persons. In the one case a fatal termination ensued; in the other, recovery followed the administration of a pill of ferric sulphate and potassium carbonate according to the formula of Blaud.

Edema of the Larynx Complicating Influenza.—Previously looked upon as of itself an insignificant affection, recent experience has taught us quite the contrary of influenza, while the complicating conditions have been of the widest diversity and fraught with great fatality. Affections of the respiratory tract have been especially common. A catarrhal condition of the larynx was almost universal. In some cases ulceration occurred, and in a small number edema has developed, necessitating tracheotomy. Two cases of edema of the larynx in the course of influenza are recorded by Cartez (*Rev. de Laryngol d' Otol., et de Rhinol.*, No. 12, 1893, p. 450), both in adults, one a male, the other a female. In both leeches and ice were applied over the larynx, and recovery ensued. In the second there was a history of previous syphilitic infection, with laryngeal manifestations, which, it is thought, acted as a predisposing cause.

REVIEWS.

GEOGRAPHICAL PATHOLOGY: AN INQUIRY INTO THE GEOGRAPHICAL DISTRIBUTION OF INFECTIVE AND CLIMATIC DISEASES. By ANDREW DAVIDSON, M.D., F.R.C.P. Ed., Late Visiting and Superintending Surgeon, Civil Hospital, and Professor of Chemistry, Royal College, Mauritius. 2 vols., 8vo, pp. 1005. New York: D. Appleton & Co., 1892.

IN this work the author has aimed to sketch the geographic distribution of infective and climatic diseases, and to trace the influence of temperature, rainfall, altitude, and soil-conditions on their prevalence, character and epidemic spread. Organic diseases of the heart, kidneys, and nervous system, which are not, as a rule, caused by infection and are not materially influenced by soil and climate, are not regarded as properly within the scope of the book, and are only occasionally mentioned. Endemic malarial fevers in various malarial countries are extensively considered, and very instructive charts, illustrating the characters which they assume in different countries, have been introduced. Typhoid fever, cholera, yellow fever, and influenza receive especial attention, and notes of other diseases of the class embraced by the author, usually proportionate to their local importance, supplement the former.

The author has considered his subject under four great geographic groups—namely, Europe, Asia, Africa, and America, with a convenient order of subdivision. For example, Europe is considered by three latitudinal divisions in twenty chapters. Each chapter of the book begins with a concise geographic description of the country in question, followed by remarks on climatology, including such points as mean monthly rainfall and temperature, a short section on vital statistics, and a more or less lengthy one on pathology. Chapter I,

which treats of Iceland and the Faröe Islands, fairly illustrates the comprehensiveness and the importance of the data collected, analyzed, and recorded in this book. Under the section of pathology, in this chapter, we have paragraphs on malaria, enteric fever, typhus fever, relapsing fever, diphtheria, croup, Asiatic cholera, dysentery, diarrhea, influenza, whooping-cough, smallpox, measles, scarlet fever, pneumonia, epidemic pneumonia, hepatitis, hydatids of the liver, diseases of the spleen, trismus neonatorum, carcinoma, rheumatic affections, scrofula, syphilis, leprosy. The special information to be gleaned from these paragraphs is that leprosy, formerly widely diffused in Iceland, is now rapidly dying out; syphilis is excessively rare, and of a mild type; pulmonary tuberculosis is seldom met with in natives; whilst measles has appeared only four times in the history of Iceland. Scarlet fever occurs only at rare intervals, and none of the eruptive fevers is endemic in the island; neither is whooping-cough endemic, nor does it show a tendency to spread, even when introduced into the country. Although there are numerous marshes among the inhabited districts, paroxysmal fevers are not endemic, and while diarrheas are comparatively rare, enteric fever is endemic, and often assumes an epidemic form; relapsing fever has never been seen, and epidemic, cerebro-spinal meningitis has been encountered only once.

While usually any one of the diseases enumerated is dismissed in a single paragraph, influenza fills something over two pages. Although the author declines to undertake to settle the dispute as to whether *influenza arctica*, so frequent in the Arctics, is a specific affection, closely allied to the epidemic disease, or should be regarded as a simple catarrh, arising from the climatic conditions peculiar to cold regions, the facts which he prefers to speak for him appear to indicate very strongly the contagious and transportable nature of epidemic influenza.

Thus, according to our author, "Influenza has often been observed to make its appearance immediately after the arrival of a foreign vessel, although the passengers and crew of such vessel may not have been suffering from the disease, and although influenza may not have been raging in the port or country from which it sailed.

"The outbreak of influenza in Iceland on the arrival of foreign vessels can only be explained on the assumption that the specific cause of the disease is transportable, but it does not follow that commercial intercourse is the only means by which this malady is diffused.

"Another remarkable circumstance in connection with the outbreaks of influenza in Iceland is the immunity from the disease enjoyed by strangers and recent arrivals, while very few of the natives escape."

It is impossible, in the short space allowable, to give any adequate review of this great work. We have quoted from the first chapter because it is short and fairly representative. These two volumes are replete from the first to the last chapter with a great mass of well-analyzed and condensed information of a trustworthy character, so desirable for the comprehensive and philosophic study of epidemic and infective diseases as they may be influenced by general climatic and telluric conditions, and yet usually so difficult and so laborious of acquisition. The great value of these two volumes is further enhanced by a very full table of contents and by a very complete cross-index.

On the whole, we believe that the aim of the author has been attained in a manner that will prove highly satisfactory to those who shall have occasion to consult these encyclopedic volumes, which, in our opinion, should be ranked with the very similar works of Hirsch and of Lambord.

In conclusion, we would most highly commend the judgment of the publishers in determining that such a valuable contribution to geographic pathology should issue from their press. The typographic excellence of this work is fully up to the high standard of these publishers.

ELEMENTS OF HUMAN PHYSIOLOGY. By ERNEST H. STARLING, M.D. Lond., M.R.C.P., Joint Lecturer on Physiology at Guy's Hospital, London, etc. With 100 illustrations. 12mo, pp. 437. Philadelphia: P. Blakiston, Son & Co., 1892.

THE importance of the branch of physiology in the curriculum of medical education cannot be overestimated, and need not here be dwelt upon. Suffice it to say, that a full and correct understanding of the subject is essential for successful practice in any department of medicine. He who lacks knowledge of structure and function can only be incompetent to treat their derangement. Books on physiology are not wanting. Of these we have numerous good ones, both in Continental languages and in English. The little volume before us may be assured a cordial welcome. It is characterized by accuracy of statement, and deals with its subject in a clear and easy style that is calculated to excite interest and hold attention. While the various subjects are discussed in a terse, concise manner, their usefulness has not been annihilated by the painful compression and abbreviation so common in elementary books of the day. The arrangement conforms to the usual one. Recent developments receive appropriate notice. The index is full. The mechanical details meet the requirements. The book is to be heartily recommended to those who wish to lay a strong groundwork in physiology.

DISEASES OF THE LUNGS, LIVER, AND KIDNEYS. By N. S. DAVIS, JR., A.M., M.D., Professor of the Principles and Practice of Medicine, Chicago Medical College, etc. No. 14 in the Physicians' and Students' Ready Reference Series. 8vo, pp. vii, 359. Philadelphia and London: The F. A. Davis Co., 1892.

WONDER must often arise as to what becomes of all the medical books published. Many can have but a limited circulation, and many more can attract but passing attention. We have before us a well-conceived and a well-written little volume, dedicated only to a consideration of the diseases of the lungs, heart, and kidneys, the *motif* for which, however, we must confess we scarcely appreciate. Just why only these three subjects should be considered together is not entirely clear, unless it be in response to an increasing tendency to specialism. There is no claim to originality, and in truth it can be said that the book contains little or nothing original. The subject-matter presented can, moreover, be found at least equally as well presented in

any of the recognized text-books on the practice of medicine. As already indicated, the several subjects are well and fairly fully considered. We fail, however, to find any reference to fibrinous bronchitis, to hydatids, sarcoma and tuberculosis of the kidney, and to floating kidney. The subjects of malformations and displacements generally seem completely ignored.

DISEASES OF THE SKIN, by CHARLES C. RANSOM, M.D., Assistant Dermatologist, Vanderbilt Clinic, New York. (THE STUDENTS' QUIZ SERIES. Edited by BERN B. GALLAUDET, M.D., Demonstrator of Anatomy and Clinical Lecturer on Surgery, College of Physicians and Surgeons, New York. Volume 8.) Pocket size, 12mo., 192 pages, 28 illustrations. Limp cloth, $1.00. Philadelphia: Lea Brothers & Co., 1893.

WE have looked over this little volume, and the thought that arises in our mind is: For what purpose was it written? Presumably to aid the student just prior to his examination at the college or hospital, but we are firmly of the opinion that all books of the character of Quiz's, or "questions and answers," fail completely to give the knowledge the student ought to have. The present book is no exception, and while the subject-matter is equal in merit to the several quiz's on this subject that have recently appeared, it offers no special attraction. The treatment is singularly neglected, and with some diseases is altogether wanting. We note that the formula of Lassar's paste is inaccurately given, while the directions for its use are different from those advised by the leading dermatologists. The nomenclature and the classification are both good, the latter being that of the American Dermatological Association.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-fourth Annual Meeting, held at Milwaukee, Wis., June 6, 7, 8, and 9, 1893.

(Continued from page 28.)

SECTION ON MATERIA MEDICA AND PHARMACY.

DR. FRANK WOODBURY, of Philadelphia, delivered the President's Address. The subject of his remarks was "Scientifically Prepared Remedies Essential to a Rational Therapeutics." He said that the daily use of instruments of precision in clinical medicine, and the study of pathology, make the demand an imperative one for greater precision in therapeutic methods. Haphazard prescribing and vulgar empiricism must yield to scientific pharmacology and rational therapeutics; these, however, depend not only upon accuracy of dosage of skilfully selected remedies, but also upon uniformity in the composition and physiologic activity of such remedial agents. The standardization of pharmaceutic preparations is as important to the physician as is the uniform composition of test-solutions to the chemist. Accuracy of dosage requires that the amount, or proportion, of active principles of any given remedy shall be uniform, in order to properly gauge its effects.

The modern physician is free from the dictum of any school in the choice or application of remedies. The ancient, assumed laws of cure have been outgrown, and it is impossible that they shall ever again be considered of sufficient importance to divide physicians into sects or schools of practice. It is true that names survive the things and circumstances that called them into being; and if some sectarian physicians may, for reasons best known to themselves, profess to represent certain schools, it is well known that they use the same text-books, read the same medical journals, get their medicines from the same sources, as others. Honest medical sectarianism could scarcely survive the revelations of modern biologic science, that all diseased processes are merely normal functions under abnormal conditions; and that such conditions are physical and natural and not spiritual or supernatural. Independence of the voice of authority other than that of trained experience and freedom to reasonably apply any scientific fact to the alleviation of human suffering, are the boasts of modern medicine and the criterion of the scientific physician. There can be only one best way to treat a patient suffering with any given disease, and it is the aim of scientific medicine to discover and apply that method, without reference to any hypothetic law of cure.

The hypodermatic tablet illustrates the scientific feature of precision of dosage in its most perfect form, while the ordinary soluble tablets have not only accuracy of administration, but convenience and cheapness in their favor. It cannot be denied that this new departure in pharmacy is working adversely to the interests of the retail pharmacist and, in the end, will not prove favorable to the physician, because it encourages him to dispense his own prescriptions and almost inevitably drives him into routine practice. It is attended by the practical disadvantage, which the physician should seriously consider, of depriving him of any documentary evidence, or, indeed, any evidence beyond his own testimony, as to the identity or character of the remedy administered, in case of a suit for homicide by misadventure, or for damages for malpractice when it is claimed that a wrong medicine has been administered. The written prescription is a safeguard, in such a case, that the physician would be glad to possess.

The mutual benefits derived from the separation of pharmacy from the practice of medicine were briefly mentioned. Physicians and pharmacists were urged to become better acquainted with each other, so as to increase respect and avoid misunderstanding.

The interests of the scientific pharmacist and the scientific physician do not conflict, but supplement each other.

PROF. J. M. GOOD, of St. Louis, Mo., read a paper entitled "Shall the Practice of Medicine and the Practice of Pharmacy continue Distinct and Separate?" and DR. L. CH. BOISLINIERE, of St. Louis, Mo., read one entitled "The Physician and Pharmacist." The position taken in each was that pharmacists, as a class, are careful, painstaking, and well qualified to stand between the prescriber and the patient, or *vice versa;* and occasions may arise when they are of great utility in this position.

At the second session, PROF. C. LEWIS DIEHL read a communication on the "National Formulary" of the American Pharmaceutical Association, which physicians would find very valuable if they were more familiar with its contents. The reliability of the formulas has been re-

cently tested by a Committee on Revision, which will defer its final report until after the appearance of the new U. S. Pharmacopeia. A preliminary report, however, was made to the American Pharmaceutical Association in which the reliability of the formulas was indorsed, with few exceptions of no importance. The physicians of the American Medical Association are earnestly asked to give this Formulary their favorable consideration, and the Association is urged to take such action as may be conducive to the adoption and use of the National Formulary by practising physicians throughout the land.

PROF. EDGAR L. PATCH, of Boston, Massachusetts, contributed an interesting paper entitled "A Few Incompatibles often Overlooked by the Physician, and some Prescription Controversies." The prescriptions were in *fac-simile*, and might readily give rise to controversy as to their exact reading, owing to careless chirography, actual mistakes and omissions, and abbreviations. The necessity of a written prescription in place of a verbal one was pointed out, and it was insisted that it should be written in good Latin, to prevent mistake and to assist in carrying out the intention of the physician. Many of the conditions affecting the therapeutic effect or physical appearance of preparations may be overcome by greater care in selecting drugs and by specifying exactly what preparation is desired by the physician.

The prescription may disappoint from a number of reasons: 1. Because the patient does not follow directions; 2. Because drugs cannot benefit the case; 3. Because the dosage is incorrect; 4. Because a wrong remedy is selected; 5. Because the remedy is deficient in strength or is over-active; or 6. Because the vices or habits of the patient neutralize or abort treatment.

PROF. J. M. GOOD made a verbal communication on "Some Additional Incompatibles in Prescribing."

PROF. FRANK RYAN, of Philadelphia, read a paper on "Cocillana," which is the bark of an undetermined species of Guarea.

The chief therapeutic value of this drug is in diseases of the respiratory tract, especially bronchitis in its subacute or chronic stage. It is a stimulating expectorant, free from nauseating or depressing effect. The dose of the tincture is from thirty minims to two fluidrams; of the fluid extract, from five to twenty minims. It has an aromatic odor and bitter taste; and in the form of fluid extract may, with advantage, be combined with syrup.

DR. F. E. STEWART read a paper, by title, "The Waters of the Glen Springs, Watkins Glen, New York."

A paper on "The Treatment of Chlorotic Anemia," by Dr. RALPH STOCKMAN, of Edinburgh, was also read by title.

A discussion upon the United States Pharmacopeia was opened by PROF. C. LEWIS DIEHL, of the Committee on Revision. He announced that the new Pharmacopeia would be issued early in the autumn, as it is rapidly approaching completion. No radical departure from the preceding revision is contemplated, but the metric system has been adopted and is employed exclusively in the various formulæ in place of parts by weight. In the directions for making fluid extracts parts by volume will be substituted for the sake of uniformity. There will be introduced a number of new drugs and preparations, including several elixirs.

In addition to methods for standardizing opium and cinchona, there will be given methods for standardizing preparations of these drugs and also those of nux vomica.

PROF. ALBERT B. PRESCOTT expressed great confidence in the value of the revision and commended it to the attention of the physicians of the United States as a book of habitual reference. It is the code of utility, and its observance belongs in a true sense to the Code of Ethics. If the "Codex Medicamentarius" were to receive, in the medical press, some share of the attention that has been devoted to the ethical code, medical literature might gain in point of practical benefit, possibly in scientific purpose. Moreover, the Pharmacopeia is a work for professional unification; it brings together not only the pursuits of medicine and pharmacy, but the researches of biology, chemistry, and hygiene.

On motion of PROF. DIEHL, the following resolution was adopted and directed to be laid before the General Association for approval:

Resolved, That the Section on Materia Medica and Pharmacy of the American Medical Association respectfully recommends that the next edition of the Pharmacopeia, soon to be issued, be at once adopted by physicians in prescribing and pharmacists in compounding. It also advises the general adoption by physicians and pharmacists of the *National Formulary* issued by the American Pharmaceutical Association, and that the teaching medical and pharmaceutic colleges adopt these works as text-books.

The following resolutions were presented by PROF. RYAN and adopted:

WHEREAS, It appears to be a growing practice for some physicians to dispense their own medicines; therefore,

Resolved, That it is the opinion of this Section that the practice referred to, except in case of emergency, is not conducive to the better interests of the practice of medicine, nor is the welfare of the patient best served by this means of medication.

Resolved, That the Section on Materia Medica and Pharmacy of the American Medical Association wishes to discourage the practice, and asks its members to use their influence to that end.

The following resolution was offered and adopted, with a view of exciting greater interest among physicians and making the future meetings of the Section more valuable:

Resolved, That, at the future annual meetings of the Section on Materia Medica and Pharmacy, special efforts shall be made to have a scientific exhibition of new remedies and of such drugs and pharmaceutic preparations as will be of an educational character, such preparations to be strictly in accordance with the Code of Ethics and to be accompanied by such lectures or descriptive papers as shall enhance the value of the proceedings and lead to instructive discussion; the same to be approved by the local Committee of Arrangements of the American Medical Association.

The officers of the Section were reëlected unanimously.

NEWS ITEMS.

A Standing Committee on Cholera.—The following circular has been issued by the College of Physicians of Philadelphia:

PHILADELPHIA, June 20, 1893.

The Standing Committee on Cholera of the College of Physicians earnestly desires to secure the organized co-operation of the physicians of Philadelphia in the efforts, in which the whole country is interested, to prevent the appearance of cholera among us in the coming summer.

A general plan has been adopted by which physicians in Philadelphia can coöperate with this Committee—and through them with the Board of Health and the other city authorities—in improving the sanitation of the city in every respect.

Physicians in each ward from the number of those volunteering for this public service will be asked to observe especially—as they may readily do in their daily rounds—the condition of the streets, alleys, sewers, and gutters, and to report to this Committee upon the performance and thoroughness of the work of the street-cleaning contractors, etc. It is also desired that they should observe, as far as possible, the sanitary condition of dwellings, especially noting nuisances which need to be immediately remedied. If cholera spread rapidly in Europe they should ascertain so far as they may be able whether there have been any recent arrivals of immigrants likely to have come from or to have passed through infected places.

Reports should be immediate, explicit, and concise. Necessary blanks for the purpose will be supplied by the Committee.

If cholera should appear in Philadelphia or in any neighboring city, further organization will, of course, be necessary. Ambulance-corps and nurse-corps will then be organized by the Committee, as well as a corps for disinfection service. Under such circumstances it will become necessary to report at once to this Committee, as well as to the Board of Health, every case of acute diarrheal disease as a "suspect."

The Committee, in accordance with the instructions of the College, waited upon the Mayor and city authorities and offered their services, both advisory and executive. They are glad to be able to state that this offer was well received by the City Government, which approved of the plan outlined in this circular, and that the Committee was urged to report upon all matters of sanitation, paving, or general cleanliness in which changes may be desirable. The municipal authorities have promised that criticisms of these matters on the part of the Committee will receive the most careful and prompt attention.

Physicians willing to coöperate with the Committee in this important matter are requested to at once forward their names and addresses to the Secretary.

Death of James McCann, M.D., LL.D.—Dr. McCann was born in 1836, in Penn Township, Allegheny County, Pa. He began the study of medicine in 1858 and graduated from the Medical Department of the University of Pennsylvania in 1863 and immediately entered the medical service of the army as assistant-surgeon of the Fifth Pennsylvania Volunteers. He continued in this service until the close of the war, when he returned to Pittsburg and began the practice of medicine with Dr. W. C. Reiter. Two years later he received the appointment of surgeon to the Marine Hospital, and the connection with Dr. Reiter was soon afterward dissolved.

For twenty years he was one of the surgeons of the Pennsylvania, the Allegheny Valley, and other railroads.

He was an active and influential member of the Pittsburg Free Dispensary from its inception, of the Board of Health for many years, of the Allegheny County Medical Society, of the State Medical Society, of the American Medical Association, of the American Surgical Association, and of the American Association of Obstetricians and Gynecologists; but, owing to ill health, he was never able to attend a session of the last.

He organized the first medical college in Western Pennsylvania, in which, in September, 1886, he was elected to the chair of Professor of the Principles and Practice of Surgery, which position, notwithstanding his failing health, and in defiance of bodily suffering, he filled until a few months prior to his death. He was unanimously nominated for appointment as "Emeritus Professor," but he died, June 13, 1893, before this action could be confirmed by the Board of Trustees of the University.

Louisiana State Medical Society.—At the recent meeting of the Louisiana State Medical Society Dr. A. B. Miles, of New Orleans, was elected President; Dr. D. R. Fox, Vice-President First Congressional District; Dr. Charles Chassaignac, Vice-President Second Congressional District; Dr. J. D. Hanson, Vice-President Third Congressional District; Dr. C. D. Orvens, Vice-President Fourth Congressional District; Dr. A. W. Jones, Vice-President Fifth Congressional District; Dr. J. W. Duprée, Vice-President Sixth Congressional District; Dr. P. B. McCutcheon, of New Orleans, Recording Secretary; Dr. A. G. Friedrichs, of New Orleans, Corresponding Secretary; and Dr. W. E. Parker, of New Orleans, Treasurer.

American Association of Genito-Urinary Surgeons.—At the meeting of the American Association of Genito-Urinary Surgeons, held at Harrogate, Tenn., June 20 and 21, 1893, the following officers were elected for the ensuing year: President, Dr. George Chismore, of San Francisco; Vice-President, Dr. L. Bolton Bangs, of New York; Secretary and Treasurer, Dr. John A. Fordyce, of New York; Member of the Council-at-Large, Dr. R. W. Taylor, of New York.

Professor Peter, a well known French clinician of Paris, and a former pupil of Trousseau, died at Paris, on June 9th, of cerebral hemorrhage; he was sixty-eight years old.

Dr. J. Madison Taylor has been elected Professor of Pediatrics in the Medico-Chirurgical College.

PULSATING PLEURAL EFFUSION.

BY J. C. WILSON, M.D.,

PROFESSOR OF THE PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

I HAVE had the opportunity of studying three cases of pulsating pleural effusion. The first I reported to the Philadelphia County Medical Society on May 8, 1889. The report is embodied in the *Transactions* of the Society, but was not published elsewhere. As the case illustrates some unusual phases in this interesting condition, I have incorporated the report in this paper. The other cases are now published for the first time.

CASE I. *Strain in lifting; pain in the left side; pleural effusion, at first serous, subsequently purulent; extensive pulsation of the side; pyo-pneumothorax; paracentesis thoracis; free drainage, interrupted by removal of tube; tense pneumothorax; resection of ribs; recovery.*—The patient was a male, aged twenty years, unmarried, Irish, a laborer in a dye-house. He was admitted to St. Agnes's Hospital March 16, 1889. His parents were living and in good health. Three years previously the patient had an attack of chest-trouble, which continued for four weeks. Subsequently his health had been good.

About six weeks prior to admission to the hospital, in lifting a large roll of cloth, he suffered a twist of the left side. He immediately experienced severe pain, which was increased on deep breathing. There was at first no cough. After a time he began to suffer from shortness of breath and from cough, unattended by expectoration, but worse at night; he was able at all times to lie down in bed. The difficulty in breathing becoming urgent, his chest was tapped on three occasions during the nine days prior to his coming into the hospital, a large quantity of fluid being removed. This fluid, he stated, was at the first two tappings clear, but on the last occasion turbid.

Upon admission the presence of a large pleural effusion upon the left side was determined without difficulty. The cardiac impulse was felt on the right side in the nipple line, and was visible in the third and fourth intercostal spaces to the right of the sternum; there were no murmurs. There was a distinct impulse having the cardiac rhythm over the whole of the left side anteriorly and laterally as far as the line of the posterior axillary fold. This impulse, which was very distinct upon palpation, was not visible; it was not felt posteriorly.

Four days later, aspiration was performed, the needle being introduced in the eighth intercostal space slightly in advance of the line of the posterior axillary fold. About three pints of foul-smelling greenish-yellow pus were withdrawn. Threatening symptoms arising, the aspiration was discontinued.

After two days the pulsation on the left side was no longer observed to the left of the nipple line, save in a restricted area in the third intercostal space. The fluid rapidly reaccumulated and pulsation returned. By means of a trocar four pints of fetid pus were evacuated; a soft-rubber drainage-tube was introduced, and the chest dressed antiseptically. Rapid improvement in the patient's general condition immediately followed. In a week he was up and about the ward. The discharge from the tube amounted to only a few drams daily, and was no longer fetid.

After the lapse of three weeks the drainage-tube became clogged and was removed, but the resident physician was unable to replace it.

Owing to absence from the hospital, I did not again see the patient until a week later. The impulse of the heart was felt in the third and fourth intercostal spaces near the right nipple. The left chest was distinctly flattened in its antero-posterior diameter, and there was again pulsation over its antero-lateral surface, extending to the posterior axillary line and synchronous with the cardiac systole. The pulsation was most distinct in the second and third intercostal spaces to the left of the nipple line, but could be faintly perceived at the base of the chest. The percussion-sounds were tympanitic anteriorly above the level of the fourth rib and flat below. Posteriorly percussion was flat.

The dyspnea increasing and the substernal pains being more pronounced, the sixth, seventh, and eighth ribs were resected for an inch in the axillary line. Upon puncture of the pleura there was an escape of air, and the wound being enlarged to permit of an examination of the cavity, it was found free from pus. The finger could reach the compressed lung, which transmitted the cardiac impulse; and a large probe, carried into the wound and gently brought in contact with the lung, moved synchronously with the cardiac systole. After the operation the heart did not return to its normal position, but continued to beat to the right of the sternum. A large drainage-tube was introduced. Suppuration was reëstablished and a small amount of pus continued to discharge by way of the drainage-tube. Distinct pulsation persisted over the upper part of the chest outside the mammillary line. The patient did well, and after a time left the hospital and was lost sight of.

The sequence of events in the foregoing case appears to have been the following: Strain in lifting,

causing laceration of the pulmonary pleura (whether pleural adhesions, set up during the sickness three years before, had any part in determining such a lesion or not cannot be decided); pneumothorax, followed by serous effusion; aspiration in the fourth week, twice repeated at short intervals; pyo-pneumothorax, with firm compression of the lung, the lower lobe of which was completely airless, and probably adherent to the pericardium; slight expansion of the upper lobe after aspiration; heart dislocated and retained in its new position by inflammatory adhesions; transmission of impulse from the displaced heart through the contracted left lung, at first to the fluid contents, and later to tensely confined air in the pleural cavity, with pulsation of the chest-wall. This pulsation was more distinct and more persistent opposite the second and third intercostal spaces, being probably there transmitted through the compressed lower portion of the upper lobe, which had contracted adhesions at that point.

The tension within the pleural cavity, which, shortly after the removal of the first drainage-tube, gave rise to flatness on percussion below the area of the adherent lung, is only explicable upon the hypothesis of a persistent rent in the pulmonary pleura.

Case II. *Croupous pneumonia of left side; pain in side; a month later signs of large effusion; pulsation; treatment by the method of Lewaschew, without success; free drainage; recovery.*—Samuel L., aged twenty-two years, a bookmaker, was admitted to a private room in the German Hospital, March 14, 1891. The family history was good as regards pulmonary disease. His mother had died of rheumatism; five brothers and sisters were all living and in good health. There was no history of tuberculosis in the family. Five weeks prior to admission the man had had left-sided pneumonia, accompanied at first by a great deal of pleural pain, and becoming after a time complicated with pleural effusion. The physician who attended him was unable to state at what period the signs of the effusion first appeared.

The effusion steadily augmented. The patient rapidly lost flesh and became much oppressed. On admission he was greatly emaciated, feeble, and anemic; there was constant distressing cough, with a small amount of mucoid expectoration. The temperature ranged between 99° and 100.5°; the pulse, between 116 and 128; the respirations, between 20 and 24. The tongue was coated; the patient had complete loss of appetite; the bowels were constipated. Upon examination of the chest the physical signs of a large left-sided effusion were found present. There was flatness upon percussion over the whole chest, in front and behind, except at the apex, where there was tympanitic resonance. The semi-lunar space was obliterated; the heart was displaced to the right side, the impulse being felt in the third and fourth intercostal spaces within the right mammillary line.

Upon auscultation, the heart-sounds were distinct. There were no murmurs. At the upper part of the chest on the left side, both anteriorly and posteriorly, was heard feeble bronchial respiration. Below the line of flatness this was gradually lost. The vocal fremitus and vocal resonance were greatly diminished over the region of flatness. On the right side there was puerile respiration, without râles. On the left side there was bulging of the lower intercostal spaces, together with distinct pulsation, perceptible both to the eye and to touch, synchronous with the heart's action, from the second intercostal space to the base of the chest, and extending, with gradually diminishing intensity, to the mid-axillary line, where it was lost. There was no pulsation posteriorly.

Careful examination was made for the signs of even a limited pneumothorax. Neither ordinary percussion nor the coin-test yielded the signs of such a condition. Succussion signs could not be elicited.

Aspiration was at once performed and thirteen fluidounces of light-colored pus of creamy consistence were withdrawn. The patient was much agitated and insisted upon the operation being discontinued. On the following day aspiration was repeated and eighty ounces of pus were evacuated. The pulsation thereupon disappeared and did not recur. This was followed by evidences of expansion of the lung, namely, vesicular murmur reaching as low as the angle of the scapula, with crepitant and sub-crepitant râles, vesicular resonance, friction-sounds, and egophony. The impulse of the heart could no longer be detected to the right of the sternum, but was felt at the left border of the sternum. The intercostal spaces were slightly retracted; the patient showed rapid improvement; the temperature fell; appetite returned; cough ceased. In the course of a few days, however, there were signs of reaccumulation of the effusion. It was then determined to treat the empyema by the method of Lewaschew, which consists in the removal of the pus and its replacement by sterilized normal salt-solution. This operation was repeated on several occasions at intervals of two or three days. It was not, however, attended with success, the pus always rapidly reaccumulating and tending, after a time, to become foul.

On April 16th the chest was perforated by means of a short trocar of large diameter, and through the canula a No. 18 soft catheter was introduced and allowed to remain. The drainage thus secured was efficient.

On May 12th the drainage-tube, which had been gradually shortened, was withdrawn, and at the end of May the patient left the hospital, well, with an absence of retraction of the chest-wall, which, under the circumstances, was remarkable. In a short time he resumed his profession as a gambler.

The chief interest in this case relates to the fact that neither in the history nor in the physical examination were there evidences of pneumothorax. The patient had been attended outside the hospital from the beginning of his sickness by a competent

and painstaking physician, who recognized the attack as one of pneumonia, and gave a clear history of sudden onset, with chills, high fever, and rusty sputum. At no time in the course of the attack had there been such purulent expectoration as would justify the suspicion that a bronchial fistula had been established, nor was there elicited upon painstaking search, even with the coin-test, the slightest indication of any collection of air in the pleural cavity. The case is of further interest because, immediately upon the reduction of the intra-pleural tension, after the aspiration, the pulsation disappeared, not to recur when, as was shown to be the case during the treatment by the method of Lewaschew, pneumothorax had been accidentally established, nor when, after the perforation of the chest-wall, a free pyo-pneumothorax existed.

CASE III. *Family history of tuberculosis; influenza followed by pulmonary tuberculosis; large left-sided effusion; aspiration of purulent fluid; pyo-pneumothorax; pulsation; large tuberculous cavity of right lung; death from hemoptysis.*—W. B., twenty-one years of age, a harness-maker, was admitted to the hospital of Jefferson Medical College, October 15, 1892. His father had died of blood-spitting; his mother, from the results of influenza. He had one sister, who was living and in good health. Until two years previously the patient had been well and strong. At that time he had an attack of influenza, which was followed by rapid and serious failure of health; digestion became disordered; he lost weight and strength and a troublesome cough developed. After the lapse of four months he began to suffer from afternoon fever; he became progressively weaker and emaciation was marked. He suffered also from exhausting night-sweats, and on several occasions had hemoptysis.

In July, 1892, he presented himself at the Out-patient Department of the hospital for treatment. It was then found that the left chest was full of fluid. Declining operative treatment, he discontinued attendance at the clinic. He states, however, that shortly afterward three quarts of thick pus were withdrawn from the chest by aspiration. Cough was constant and troublesome and accompanied by abundant muco-purulent expectoration. He stated that at intervals he expectorated large amounts of fetid pus.

The patient, upon admission, was extremely emaciated and anemic; cough was constant and troublesome; he suffered from hectic fever and profuse night-sweats. Upon physical examination, the signs of pneumothorax with fluid upon the left side were found present; the respiratory excursus was extremely limited; the lower intercostal spaces were obliterated. Above the level of the fourth rib the percussion was tympanitic. In this region there was amphoric respiration and a typical response to the coin-test. The succussion-splash was easily developed. Below the level of the fourth rib there was flatness, which extended two fingers' breadth below the arch of the ribs, obliterating the semi-lunar space of Traube. There were signs of a large cavity at the right apex; the heart was displaced to the right, the impulse being distinct in the fourth and fifth intercostal spaces to the right of the sternum. The heart-sounds were most distinct at mid-sternum, and were well heard to the right of the sternum; there were no murmurs.

Upon inspection, there was distinct pulsation of the chest, synchronous with the heart's action, in the third, fourth, fifth, and sixth intercostal spaces on the left side, extending to the line of the anterior axillary fold. Pulsation, though not visible elsewhere, was perceived upon palpation at the arch of the ribs on the left side.

Some days after admission, about eight ounces of fetid pus were removed by aspiration. After this the pulsation became less marked. The patient declined operative interference, and owing to his wretched condition, it was not urged.

The patient left the hospital in December. Late in January he was readmitted, and died suddenly from pulmonary hemorrhage on February 25, 1893. An autopsy was not permitted.

With the assistance of Dr. A. A. Eshner, I have collected 68 cases of pulsating pleural effusion. Dr. Eshner has made the following analysis:

Of the 68 cases, the sex is stated in 52. Of these, 41 were males; 11 females.

The age is given in 47 cases. It varied from 2 to 57 years.

The cases were distributed among the quinquennial periods as follows: Up to 5 years there were 3; between 6 and 10, 2; between 11 and 15, 2; between 16 and 20, 3; between 21 and 25, 16; between 26 and 30, 8; between 31 and 35, 4; between 36 and 40, 5; between 41 and 45, 1; between 46 and 50, 2; between 51 and 60, 1.

The side affected is named in 66 cases. Of these, the left was affected in 61; the right, in 5.

The character of the lesion is stated in 67 cases; of these, 37 were of the nature of empyema necessitatis; 28 were intra-pleural. In 2 cases both varieties of pulsation were present.

Of the 5 cases in which the right side was affected, 3 were of the nature of empyema necessitatis; 1 was intra-pleural; and in 1 both varieties were present.

In 35 of the cases of empyema necessitatis the number of tumors is stated. In 28 there was 1; in 5 there were 2; in 2 there were 3.

The outcome is stated with more or less definiteness in 46 cases. Of this number, recovery took place in 24; death in 22.

Of the total number of cases, 1 was reported in 1640; 1 in 1810; 3 between 1840 and 1849; 14 between 1850 and 1859; 8 between 1860 and 1869; 10 between 1870 and 1879; 23 between 1880 and 1889; 8 since 1890.

The pulsations are synchronous with the ventric-

ular systole. As a rule, they may be detected alike upon inspection and palpation. Sometimes they are not visible, but may be recognized by palpation only. When intra-pleural, the pulsation may be limited to two or three intercostal spaces. More commonly it occupies the greater part of the anterior aspect of the thorax as far to the left as the anterior axillary line. In some cases it has occurred posteriorly, and, in a few instances, as in the cases reported by Rees,[1] by Courbon,[2] and in one referred to by J. M. Barton, a pulsating empyema necessitatis existed in the left lumbar region. Frequently the pulsation is only of moderate force, requiring some attention for its recognition. In some of the cases, however, it has been forcible.

In the majority of cases the left side was affected. Comby, writing in 1889, said: "Il faut ajouter que les pleurésies pulsatiles sont toujours situées à gauche; on trouverait peut-être une exception à cette règle, on aurait de la peine à en trouver deux."

Of the 66 cases in which the side is designated, the left was affected in 61 and the right in 5, or 8.2 per cent.

Most of the cases are reported as cases of pulsating empyema. Of 41 cases, in which the notes refer to the character of the pleural contents, in 37 it is said that pus was present; in 1, yellowish, fetid fluid; in 1, caseous matter; in 1, bloody serum; in 1, turbid fluid. In the remaining 27 cases nothing has been noted of the character of the pleural contents.

Pulsating empyema has been mistaken for aneurism of the aorta. Only in exceptional cases does the differential diagnosis between these two conditions present serious difficulty. Aneurism of the aorta bears a definite relation to the central long axis of the chest; its invasion of regions of normally clear percussion is circumscribed; it is usually the seat of murmurs or other sounds synchronous with the rhythm of the heart. The signs of pulsating empyema, whether intra-thoracic or an empyema necessitatis, are, on the other hand, usually upon the left side and at a distance from the median line; the percussion-dulness is uniformly at the base of the chest and extended, and murmurs are not present. Empyema necessitatis is influenced by pressure and by the respiratory movement of the chest-wall; aneurism is not.

Difficulty as to the differential diagnosis between pulsatile empyema and thoracic aneurism can only arise in the case of an encysted empyema in close relation with the heart.

The anatomic conditions underlying pulsation in pleural effusions are: First, some degree of paresis of the intercostal muscles, such as occurs only in large pleural effusions usually of long standing. Second, local necrosis and perforation of the parietal pleura (empyema necessitatis); in both these conditions there is relative weakening of the wall of the chest. Third, pneumothorax, either latent or manifest; this condition has been observed in a majority of the cases; in a small number it has been apparently absent; in Case II of my series it was carefully sought for, but not found. Fourth, an atelectatic condition of the lung in whole or in part, the left lung being in relation with and adherent to the pericardium.

In Case I of my series the persistence of the pulsation in the upper intercostal spaces after Estlander's operation had been performed is to be explained by the fact that a strip of adherent and compressed lung extended from the pericardium to the point in question.

Numerous theories have been advanced in explanation of the phenomenon of pulsation in pleural effusions:

1. That of Traube, which attributes the pulsation to the condition of the heart and the pericardium; but cardiac hypertrophy and pericardial adhesions, far from being the rule, have been the rare exception, though pleuro-pericardial adhesions, as in all general pleurisies, have been noted.

2. A second theory attributes the conduction of the pulsations to the compressed and carnified lung, but as compression and carnification, with pleuro-pericardial adhesion, take place in all massive effusions, this condition cannot be invoked to explain the occurrence of a phenomenon so rare as that of pleural pulsation. This was the theory first advanced, but afterward withdrawn, by Comby.

3. The theory of Féréol assigns the pulsation to a pneumothorax of moderate extent, which may often be latent. The pulsation is here attributed to the transmission of the cardiac impulse through the confined air in the manner in which compression-waves are transmitted through the rubber apparatus of the cardiograph and other similar instruments. That this theory is insufficient, becomes manifest from the fact that in the majority of the cases of effusion with pneumothorax, pulsation is absent, and in certain of the cases, notably in Case II of my series, pneumothorax, as shown by the history of the case and by most careful search, did not exist.

4. The fourth theory attributes the pulsation to a variety of associated pathologic conditions: paresis of the intercostal muscles; intrapleural pressure; the energy of the heart's action. But weakening of the chest-wall and enfeeblement of the intercostal muscles are common conditions in old empyemata. Forcible action of the heart, far from being the rule in pulsating empyemata, is the exception, and as to

[1] British Medical Journal, Aug. 21, 1858, p. 703.
[2] Gazette des Hôpitaux, May 24, 1870, p. 237.

intra-pleural tension it is variable in pulsating effusions, and occasionally absent altogether.

To sum up, no one of the theories hitherto advanced is adequate to account for the rare phenomenon of pulsation in pleural effusion. We must await facts not yet brought to light to fully explain its mechanism. Among the conditions not hitherto noted which favor pulsation are (*a*) strands of atelectatic lung-tissue, reaching from pleuro-pericardial adhesions at one extremity by way of pleural adhesions at the other to the surface of the chest, and thus acting as conductors of the cardiac impulse, and (*b*) the elasticity of that part of the wall of the thoracic cavity on the left side, formed by the diaphragm in its relation to the fundus of the stomach. The latter condition, together with the convexity of the left wall of the heart in systolic tension and the almost synchronous diastolic tension of the aorta on the left side of the chest, as pointed out by Toft and Wintrich, serves to explain the greater frequency of pulsation in left-sided effusions.

UNILATERAL HYPERTROPHY OF THE FACE.

BY D. W. MONTGOMERY, M.D.,
PROFESSOR OF DISEASES OF THE SKIN AND SYPHILIS, POST-GRADUATE MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA.

UNILATERAL hypertrophy of the face is a much more unusual disease than its opposite, unilateral atrophy. In the accessible literature I have been able to find records of only a very few cases, and these few have been reported in Germany. It is not likely that the affection is confined to the German branch of the Teutonic family, but rather that greater interest is taken in medicine in Germany than in any other country, and that consequently a much larger number of rare and curious cases are collected, a circumstance long ago pointed out by Virchow, in speaking of the collection of material for writing a treatise on neoplasms. One of the cases of hypertrophy of the face was in fact a Lett, reported by a doctor living in the Russian Baltic provinces;[1] a matter of interest in connection with the recent extinction of the University of Dorpat, from which so much good work has emanated.

The interest in these cases lies in their exceeding rarity, and also in their presumable relationship to unilateral atrophy, to which so much thought and investigation have been given. It is by the careful reporting of such cases whenever found that some future collaborator may be enabled to draw valuable inferences as to the trophic functions of one of the most interesting nerves of the body, the fifth.

I have been able to find mention of only nine cases of this affection, seven of which were congenital, one commencing in the second year of life with no apparent cause, and one following neuralgia of the fifth nerve.[1]

On November 10, 1892, Dr. F. J. Hund sent me Gustav W., aged thirty-one, born in New York, of German parents. He is the eldest of a family of eleven children, five of whom are yet alive. There was no accident during the pregnancy,[2] and the patient was born at term without the aid of instruments. There are no other deformities in the family. The man has a pale, "café au lait" complexion, and both a brother and a sister that I have seen are also pale brunettes.

The patient is stoutly and, with the exception of

[1] Dr. med. Ernst Kiwull, assistant in the City Hospital, Riga.

[1] The following is a list of these cases:

1. Beck's case, congenital, reported in Med. Annalen von Puchelt, Chelius und Naegele, in the year 1836. Quoted by Ziehl, Virchow's Archiv, vol. xci.

2. Friedreich's case, congenital, reported in Virchow's Archiv, 1863. Quoted by Ziehl, Virchow's Archiv, vol. xci.

3. Heumann's case, congenital, reported by Friedreich with the foregoing case. Quoted by Ziehl, Virchow's Archiv, vol. xci.

4. Passauer's case, congenital, reported in Virchow's Archiv, 1866. Quoted by Ziehl, Virchow's Archiv, vol. xci.

5. Berger's case, following neuralgia of the trigeminus, reported in the Deutsche Archiv f. klin. Med., 1872, ix, p. 393. Quoted by A. Eulenburg in his article on "Hypertrophy of the Face," in Eulenburg's Real-encyclopädie, vol. viii, p. 384.

6. Fisher's case, congenital, reported by Prof. Dr. H. Fischer in the Deut. Zeitschrift f. Chirurgie, 1874, Bd. xii, p. 9.

7. Ziehl's case, congenital, reported by Dr. Franz Ziehl in Virchow's Archiv, 1883, vol. xci.

8. Schieck's case began toward the end of the second year of life, and is reported in the Berliner klin. Wochenschrift, 1883, Bd. xx, p. 700.

9. Kiwull's case, congenital, reported in the Fortschritte d. Medicin, 1890, Bd. viii, p. 121.

The case mentioned by Hüter (Grundriss d. Chirurgie, Bd. ii, p. 57) has been purposely omitted on account of insufficient data.

Stilling's case, reported in his work on "Spinal Irritation," published in Leipzig in the year 1840, can hardly be considered a case of unilateral hypertrophy, as there was enlargement and increase of the bloodvessels following a blow from a stone. The case is, therefore, as Ziehl says, vasomotor, and not trophic in origin.

The crossed hypertrophies (see a case reported by G. Lewin, Charité Annalen, No. 9, annotated in Virchow-Hirsch, Jahresbericht, 1884; and also a case reported before the Copenhagen Medical Society, by Dr. D. E. Jacobson, annotated in the Pacific Medical Journal, March, 1893), and those hypertrophies implicating also an arm or a leg, or even the entire half of the body, are excluded from consideration in this paper.

Jonathan Hutchinson and Alexis Thomson report one case each of unilateral hypertrophy of the skull. The history in Hutchinson's case is so meager that one cannot tell if the hypertrophy was confined entirely to the distribution of the fifth nerve or not.

The history of Thomson's case is fuller, and, although he does not say so in so many words, one might reasonably infer that there was no other hypertrophy present, no hypertrophy either of the trunk or of the limbs. Thomson was fortunate in securing an autopsy in his case, but no investigation of the fifth nerve seems to have been made.*

[2] In Passauer's case, the mother while pregnant had been crushed against a wall. The child, however, was born at term.

* Atlas of Clinical Medicine, by Byrom Bramwell, M.D., vol. ii, part i, p. 6.

his face, symmetrically built, and enjoys good health. At two years of age he had "brain fever," and was twice given up by the physicians. He has never had any other severe illness in his life, and neither he nor any of his family remember his ever having received a severe blow upon, or contusion of, the head.

The man has never suffered from neuralgia. There is a deep sunken scar on the left cheek over the inferior maxilla, the result of an abscess that formed at eight or nine years of age. His mother says that much pain attended the expression of the contents of this abscess, but further than this there is no recollection of any pain or neuralgia. The mother was closely questioned as to the first dentition, and she asserted positively that the teeth came all right.

The first sign of the disease noticed was an enlargement of the gums at ten years of age. A photograph taken at about five years of age shows the full face looking absolutely symmetrical. In another tintype, taken at fourteen years of age, the left eyebrow appears to be normal, but the mother says the deformity of the left side of the face (which is partly turned away in this picture) was noticeable at twelve years, and has been growing steadily more marked ever since.

The deformity can all be included in an irregularly quadrilateral figure, bounded by a line starting on the top of the head at the anterior extremity

FIG. 1.

of the sagittal suture, running downward and forward along the middle of the forehead, and so on down the nose to the lower border of the chin, then from the chin upward and backward along the lower border of the inferior maxilla to the tip of the left mastoid process, and thence upward to the point of commencement, the anterior extremity of the sagittal suture.

The supra-orbital, malar, and mental regions show the most marked hypertrophy. At these points the tissues are raised up in large tumefied masses, and not alone the soft tissues, for the bones themselves can be felt to form part of the deformity. Fig. 1 shows how decidedly unilateral the affection is, for especially on the forehead and nose it comes just up to the median line. The deformity of the upper lip and of the gum encroaches slightly on the right side, but only slightly.

Some idea of the amount of enlargement of the face in this case may be gained by stating that the distance from the philtrum to the tragus is six and one eighth inches on the left side, and only four and seven-eighths inches on the right.

The skin of the entire left side of the face, with the exception of that covering the lower posterior portion of the cheek over the masseter muscle, is

FIG. 2.

rough, coarse, thickened, in some places even tumefied, somewhat darker than on the other side of the face, and the hair, both lanugo and otherwise, of this altered skin is abnormally coarse. The roughened, coarse, rather dark appearance of the skin is due to several factors, of which first might be mentioned a number of flattened elevations, particularly well seen on the cheek, which will be referred to again in speaking of the microscopic anatomy of the skin. Other causes of this rough appearance are the thickening, which can be appreciated on pinching up the skin; the enlarged mouths of the sebaceous follicles, giving the skin a "saddle-leather" look; comedones, of which there are a great number; and finally, the coarseness of the hair. The lanugo hairs are so stout on the left side of the nose, and on the upper part of the left ear, that the man often has to clip them.

The most marked bony enlargements are seen on the forehead. Michael Angelo himself is outdone by a supra-orbital ridge that projects away forward, and is surmounted by a particularly shaggy eyebrow, coming well down on the root of the nose. This, with the tumefied condition of the soft parts of the malar region, and also the enlargement of the malar bone, places the eye at the bottom of a deep cavern, and gives it a particularly sinister, threatening look.

The whole expression of the right side of the face is one of peace and contentment; that of the left, one of gloom and ferocity. The entire external surface of the frontal bone is roughened, and besides this it has two immense enlargements on it. One of these is at the inner extremity of the supra-orbital ridge and is rounded, smooth, and projects forward like a blunt horn. It is well seen in the profile view of the right side of the face (Fig. 2). There

is an immense smooth roll of bone running upward, backward, and inward from the outer extremity of the supra-orbital ridge, to be lost in the general surface of the skull in the neighborhood of the anterior extremity of the sagittal suture.

The scalp and the hair of the head are normal.

The enlargement of the shell of the left ear (Fig. 3) is confined to its upper half, and is undoubtedly caused by hypertrophy of the cartilage, for the skin covering it is normal, with the exception of the lanugo hairs already mentioned.

FIG. 3.

Photograph taken five years ago.

The left palpebral fissure is narrowed by the growth downward of the upper lid, especially of its inner half, which gives the outer angle an uptilted appearance well seen in Fig. 1. This hypertrophy involves the free border of the lid, and forms a number of nodular outgrowths, out of which the coarse eyelashes project at different angles. The outer half of the lower lid is hypertrophied, but not so decidedly as the inner half of the upper lid.

Dr. H. L. Wagner kindly examined the eyes and nose for me, and found that a slight blurring of the field of vision of the left eye is due to the faulty removal of the lachrymal secretion by the deformed upper lid. He also found that there is an excavation of both discs, more marked upon the left than upon the right. There is no engorgement of the discs, the bloodvessels being perfectly normal and showing no evidence of intra-cranial pressure. This is an important point which I wish to accentuate, because of the very prominent part that hypertrophies of the hypophysis seem to play in giant growths, in akromegaly, for instance. In all other respects the eyes are normal; the media are clear; the movements of the eyeballs are faultless; the pupils react to light, and in accommodation; and the conjunctivæ are sensitive.

The enlargement of the left nasal bone and of the corresponding cartilage causes the nose to appear more flattened, and to join the cheek at a much more obtuse angle on the left side than on the right, and also narrows the left naris. Except for this narrowing of the left naris Dr. Wagner found the nasal passages absolutely normal. The left nasolabial sulcus forms a striking feature, being very deep, and at its lower angle the skin is warty, resembling the condition sometimes seen in elephantiasis.

In some of the cases observed there has been found an increased flow of saliva on the affected side. No such increase of spittle was noticed in this case, for the mouth was not abnormally wet. The left corner of the mouth was moist, but this was due to the angle being dragged down by the heavy tissues. The action of the mimic muscles was necessarily interfered with by the increased thickening and weight, but no paralysis could be detected—the patient could draw back the corners of his mouth, elevate his upper lip, and protrude his lower lip, whistle, etc.

The inferior maxilla is enlarged and roughened from the symphysis back to about the middle of the body; thence backward it seems to be normal.

The teeth are very good and are not hypertrophied, but the left upper alveolar process, with its gingiva, is immensely enlarged. The gum is enlarged both internally and externally; the enlargement of the external surface begins at the right border of the right central incisor, and bows away out forward under the upper lip, which is stretched tightly over the alveolus when the patient laughs. This part of the gum is very rough, and there is a good deal of white epithelium on it, forming leukoplasic-like patches. There is a rough projection on the anterior surface of the lower gum to the left of the median line. The hard palate behind the front teeth is a good deal more ridged than normal. Laterally, the hypertrophied gum projects as an immense tumor into the roof of the mouth.

FIG. 4.

Showing hypertrophied gum of the upper jaw. (From a photograph made from a cast by Dr. A. H. MILLBERRY.)

The left wisdom tooth and the second molar tooth are outside the line of articulation with their opponents, and, possibly because of lack of support and resistance from those opponents, have also fallen below the level of the other teeth of the upper jaw. The upper first molar was extracted two years and a half ago by the man's dentist, Dr. A. H. Millberry, and at that time the second upper bicuspid and all three molars were entirely covered in by the hypertrophied gum. Dr. Millberry removed this covering in large lamellæ, without pain and without bleeding. The patient says he does not remember ever having seen these teeth till then.[1]

[1] The alveolar process was enlarged in Friedreich's, Passauer's, and Kiwull's cases.

There is no hypertrophy of the tongue, and the tonsils are normal.[1]

No derangement of the senses of touch, heat, cold, pain, localization, taste, smell, or hearing could be found.

The patient believes that he perspires more freely on the left side of the face than on the right, and that he always wipes the perspiration from the left side of the face first.

Both the patient and his friends, and among them Dr. Millberry, who has known him for a long time, say that the deformity, especially of the frontal and malar regions, is slowly but distinctly progressing.

Dr. Hund took out large pieces of skin from the malar region, upper lip, and chin, which greatly improved the patient's appearance. Whenever, during the operation, the skin happened to be squeezed, a large amount of sebaceous matter oozed out of the openings of the fat glands.

The microscopic sections which I prepared from the tissue removed by Dr. Hund showed an immense increase of the sebaceous glands, especially of the chin; the sections were extremely brittle, easily breaking along the sebaceous glands when the cover-glass was pressed down; and it was also noticed that in introducing sutures into this part of the face after the operation, the needle passed through much more easily than through either the skin of the lip or of the malar region. The brittleness and the lack of resistance to the needle were attributed to the increase of the sebaceous glands. In all of the pieces removed there was a considerable amount of round-celled infiltration in the course of the bloodvessels.

The little tumor-like elevations of the skin of the cheek, already mentioned, were, on microscopic examination, found to be due to comparatively large masses of concentrically arranged epithelial cells, which had undergone hyaline degeneration, and which were lying in the sebaceous glands. These masses seemed to act like foreign bodies, for the surrounding connective tissue was richly infiltrated with round cells.

The epithelial layers of the skin were not thickened, except along the verrucose portion of the naso-labial sulcus, and there was no increase of pigment in the Malpighian layer. Therefore the hypertrophy of the soft parts is to be referred to an increase in the size of the hairs and of the sebaceous glands, and also to the plugging of the sebaceous glands with sebum and with degenerated cells, and probably also to an increase of the connective tissue and fat.

That this case is progressive there can be no doubt; all the evidence I have been able to gather has been affirmative on this point. It seems equally certain that it is not a congenital case, and in this it differs from all other cases reported, excepting those of Schieck and Berger. It seems improbable that it could have existed even to a slight extent in such an exposed situation as the face for so long a time—up to ten years of age—and have escaped not only the mother's but also the camera's eye.

The etiology of the condition is obscure, for we can hardly admit, with our present knowledge of the disease at any rate, either the "brain fever" or the abscess of the cheek as causes; the latter seems to be the more probable cause, because it occurred a short time before the enlargement of the gum was noticed, and it might have acted as a trauma, or like the neuralgia in Berger's case; yet it does not appeal very strongly to one as a cause. We have here, therefore, a case of progressive unilateral hypertrophy of the face, not congenital, not having any demonstrable cause, and not complicated by hypertrophy of any other part of the body—the direct analogue of progressive unilateral atrophy.

Up to the present there has been only one post-mortem examination in a case of unilateral hypertrophy of the face,[1] and that, unfortunately, was incomplete. There has, however, been a post-mortem examination in a case of progressive unilateral atrophy, a monument of well-directed industry, by Mendel.[2] In this case there was found a proliferative neuritis of the branches of the fifth nerve, especially of the second division, corresponding to the area of the greatest intensity of facial atrophy. The roots and the nuclei of origin of the fifth nerve were all normal, with the exception of the *substantia ferruginia* and the descending root on the affected side, which were atrophied. We may therefore infer, until proof to the contrary is presented, that in this case of progressive unilateral hypertrophy these same nerves are affected in some way unknown to us, the lesion possibly being irritative, and not atrophic, as in Mendel's case.

[1] There was unilateral hypertrophy of the tongue in Friedreich's, Heumann's, Passauer's, Ziehl's, and Kiwull's cases.

There was enlargement of the tonsils on the affected side in Friedreich's, Ziehl's (enlarged and also progressive), and Kiwull's cases.

[1] Friedreich's case.

CYLINDROIDS IN THE URINE, AND THEIR SIGNIFICANCE.[3]

BY ALFRED STENGEL, M.D.,
INSTRUCTOR IN CLINICAL MEDICINE, UNIVERSITY OF PENNSYLVANIA.

CYLINDROIDS, so named from their resemblance to tube-casts, or "cylinders," are peculiar bodies first found in the urine of patients suffering from scarlet fever, by Thomas,[1] of Leipzig. Similar bodies had been previously noted by Meyer,[2] Lehman,[3] Frerichs,[4] Wyss,[5] Bock,[6] and Obermeyer,[7] in various conditions, but no accurate and systematic description had been published prior to the appearance of Thomas's paper. Subsequently, Pollak and

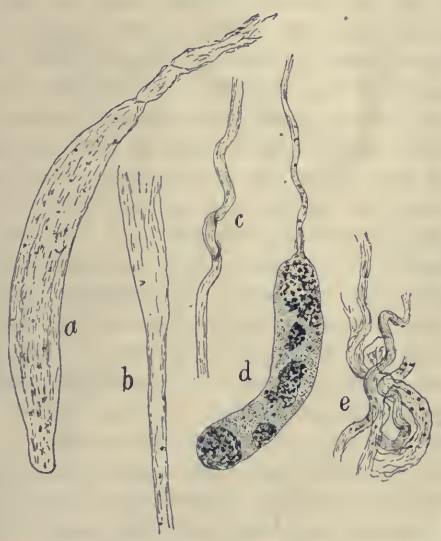
[3] Read before the Pathological Society of Philadelphia.

Török[8] gave the subject careful investigation and experimented with animals to determine the nature and origin of these bodies. With the exception of these investigations, however, the question of the significance of cylindroids has of late received little attention.

The appearance of cylindroids is even more varied than that of true casts, but a regular succession of changes may be traced from one kind to others at first sight altogether different. It is possible, however, to distinguish certain types, which serve well for purposes of description, and we may consider them as of three forms:

1. The most frequent variety appears as thin, thread-like, or filamentous bodies, composed of transparent material, sometimes faintly striated, more frequently hyaloid, and always of considerable length. They may be traced for long distances across the slide and finally taper to a fine point or disappear from view by their extreme transparency. Sometimes they occur singly; more frequently they are in clumps in which the individual fibers are so massed together as to be inseparable from each other. Occurring singly, or even in small clumps, this form may be easily overlooked if too much light or too high a power is used in the examination. A lens of one-fifth inch focal length is to be preferred, and the light should not be central and intense.

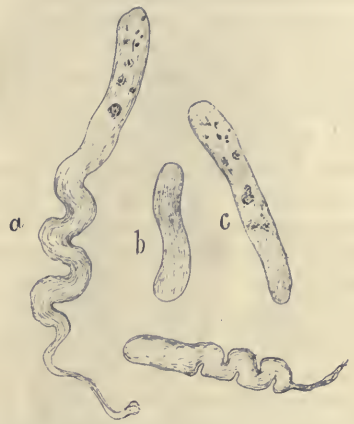
Fig. 1.



Albuminous urine. *a*, *b*, and *c*. Ribbon-like forms. *d*. Cast-like form, with cells upon surface. *e*. Filamentous forms in a clump.

2. Next in point of similarity is a form that appears as ribbon-like structures, composed of material like the last, but more generally striated and evidently flat or "ribbon-like." They are frequently crooked or bent, and often tortuous. When bent at a sharp angle the edge of the cylindroid may be turned upward and clearly demonstrate the flatness of the body. The tortuosity is sometimes marked and appears simply as an exaggeration of what we are accustomed to see in some hyaline casts. The striations are fine longitudinal streaks, which are just distinct enough to give a general shading to the cylindroid, without becoming apparent as distinct lines. This peculiar, shaded, transparent structure is quite characteristic, when once one is accustomed to observe it.

Fig. 2.



Non-albuminous urine. Cast-like forms, with deposit of urates.

Not rarely, this form presents the appearance of collapsed tubes of transparent material, not unlike, in this respect, the fibrinous casts of membranous bronchitis, though, of course, much more delicate and therefore completely collapsed. In size they vary from that of the narrowest to that of the broadest tube-casts, and they are sometimes much broader than any tube-casts I have ever seen. Like the filamentous form, they are long and occasionally, though more rarely, aggregated in masses. They may be forked or branched at the ends, and may even break up into a distinct leash, as seen in Fig. 1 (*b*).

3. A third, or cast-like form, is distinguished by its more marked resemblance to true casts, either hyaline or granular, and with this form I shall be mainly concerned in speaking of the importance of recognizing cylindroids. It is much shorter than the others, striations are more rarely present, and the appearance, as, indeed, the nature of the body, is rather that of a solid cylinder. The resemblance to hyaline casts is most striking, but these cylindroids may, in nearly all cases, be distinguished by the fine tapering end, or, if there is an abrupt ending, by the filamentous projection or tail, as is well shown in Fig. 1 (*d*). Unfortunately, however, it sometimes happens that the resemblance to a cast becomes

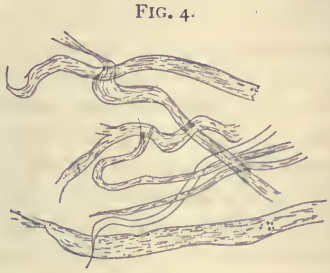
complete by the absence of the tailed extremity, as may be seen in Fig. 2 (*b* and *c*), and Fig. 3 (*a*). In such case there remains only the somewhat peculiar transparency or translucency to make the distinction, and this is a matter of doubtful value. I believe that there are certain forms that cannot be distinguished from true casts.

FIG. 3.

Non-albuminous urine. *a* and *b*. Cast like forms. *c*. Filamentous.

Each of these forms is liable to alteration by the presence in the urine of various deposits, which may cling to the cylindroids, as they do also to casts. In cases in which there is considerable deposit of urates the latter may so cover the cylindroid as to produce the appearance of a granular cast, either pale or dark, according to the quantity of deposit. As a rule, however, the urate granulation is readily distinguished by the halo that surrounds each particle, and that is doubtless due to the refractive property of the granules. In other cases oxalate crystals are seen upon the cylindroid, and in still others epithelial cells or leukocytes, when the appearance is most strikingly like that of an ordinary cellular cast (Fig. 1 (*d*).

FIG. 4.



Filamentous and ribbon-like cylindroids.

The recognition of cylindroids is rarely difficult, if ordinary care be taken. The filamentous form may be overlooked if too much light is used, but, if seen, can scarcely be mistaken for anything else. The tape-like form might, under the same circumstances, be taken for a hyaline cast, from the fact that only a part of its length might be visible; but the peculiar striation, the bends and the tortuosity ordinarily make its recognition easy. The presence of clumps or masses either of this or of the last-named form would make the nature of the body still more manifest. In the third or cast-like form the difficulty, however, is considerable, and there are cases, as I have said, in which no distinction can be made. In these instances the abundant presence of other cylindroids of unquestionable type would incline one to regard the doubtful body as a cylindroid, though it must not be forgotten that cylindroids may be found in association with undoubted casts. If the body in question has a filamentous end or tail, I should not hesitate to class it as a cylindroid.

It might properly be asked what proof there is that cylindroids of the completely cast-like appearance ever occur, and on what ground they are distinguished from true casts. I can only answer that I have found in the non-albuminous urine of patients, not at all presenting the clinical manifestations of chronic nephritis, an abundance of cylindroids of the filamentous and tape-like form, and then an occasional one having the appearance represented in Fig. 2 (*b* and *c*) and Fig. 3 (*a*). Indeed, the two cases from the urine of which these figures were drawn strikingly bear out this view. In neither was there any albumin discoverable by cold nitric acid, heat and nitric acid, or the test with trichloracetic acid (which I believe is very delicate); neither presented clinical features to be ascribed to nephritis, and in each there were many undoubted cylindroids, with a few such as those here pictured. I am of the opinion, then, that there are cylindroids of this type whose nature and significance are similar to those of the other forms. This sugests the inquiry as to the possibility of such cast-like forms occurring unassociated with manifest cylindroids; but as we have no definite criterion by which they could be distinguished from hyaline casts proper, we should for the present be compelled in such cases to regard the structures seen as hyaline casts, whether the urine be albuminous or not.

The formation and origin of cylindroids were carefully considered by Thomas, and later by Pollak and Török. The latter instituted experiments on animals to determine the place and manner of their formation, and definitely settled the matter by finding them in the renal tubules, in sections of the kidneys of animals poisoned with turpentine and other irritants. The form alone would suggest this, without the definite proof. Their composition seems to be like that of true casts, from the fact that they dissolve readily in acetic acid, as do casts. This test at the same time disposes of the view that they are composed of mucus, and the name "mucous cylindroids" is, therefore, improper. In some

cases the cylindroids do not so readily dissolve in acetic acid, and Pollak and Török sought to show that such forms differ from the ordinary cylindroid in taking origin in the various tubular glands connected with the urinary mucous membrane, but this view yet lacks proof. Whether the cylindroids produced in the renal tubules are composed of substances derived directly from the blood, or of excretions of the epithelial cells, practically reopens the old discussion of the same question in regard to tube-casts, and the truth will probably be found in accepting both theories—the blood and the epithelial cells each take part.

Thomas, as well as later observers, conceived the possibility of true casts being formed by the folding together and fusion of cylindroids, and pictured forms like that shown in Fig. 2 (*a*) to prove this possibility. It seems probable enough that such an occurrence might take place occasionally or even frequently, but the matter at present lacks substantial proof. It is not unlikely, on the other hand, that a process of moderate activity might produce in the tubules hollow casts that, later, might collapse and form ribbon-like bodies; whereas, in more rapid and severe inflammatory conditions, an immediate output of excretory material might give rise to solid cylinders. All of this, however, is speculative.

The disease-conditions with which cylindroids have been found associated have been most varied, and it has been said that they occur in healthy urine. To the latter, Thomas objects that the patient or the physician himself might easily overlook some trifling affection, when in reality renal irritation could, by careful examination, be shown to exist. I have myself never seen cylindroids in urine that seemed perfectly normal in other respects. I have found them most commonly and most abundantly in urine in which there was excess of urates or oxalates; and since my attention has been directed particularly to their study, I have rarely failed to find at least a few cylindroids in such cases. As already mentioned, Thomas found them in the urine in scarlet fever, and after him other observers encountered them in various infectious diseases. Sometimes they occur in cases of undoubted nephritis before casts make their appearance; after the latter have disappeared in convalescence; or associated with casts throughout the case.

It will have been noted that in all of the diseases with which cylindroids have been found associated, we have reason to think that there is renal irritation. In the infectious fevers, particularly scarlatina, degeneration of the epithelium of the tubules is almost a constant feature; in nephritis it is most marked; and, according to the view of most clinicians, the presence of an excess of uric acid or urates occasions irritation of the lining cells of the uriniferous tubules, as of the bloodvessels. It is precisely in the class of cases that Da Costa[1] has recently described under the title of "The Albuminuria and Bright's Disease of Uric Acid and of Oxaluria," that cylindroids occur most abundantly, and in these the clinical evidence of renal irritation is certainly considerable. Of the pathologic conditions present in these cases Da Costa says: "I think [the condition is] essentially a congestion of the kidneys, with, should the hyperemia persist, slight local inflammatory changes in the vascular cortex from the irritating effects of excreting increased amounts of ill-formed or broken-down tissue in the shape of urea, uric acid, or, these imperfectly oxidized, as oxalates." These conditions, according to my belief, are the cause of the occurrence of cylindroids; and the latter, I contend, do not occur in urine when such or similar renal conditions are absent. The presence or absence of albumin or its amount cannot, in most cases, be taken as a measure of the degree of renal irritation, and we find cylindroids when there is little or no albumin, as well as when there is a considerable quantity. In the infectious diseases the percentage of albumin is probably a better indication of the degree of irritation or disease, and Thomas found in scarlet fever, first, moderate albuminuria with cylindroids; later, more albumin and tube-casts; and, during convalescence from the nephritis, again diminishing amount of albumin and return of cylindroids, with absence of the casts, until finally all abnormal constituents disappeared.

In the cases of lithuria and oxaluria with which I have found cylindroids prominently associated, there have been some presenting a high degree of albuminuria and a larger number in which the presence of albumin could not be detected by any test. This point has already been referred to, and such cases as those from which Figs. 2 and 3 were taken have doubtless frequently been put down as instances of nephritis without albuminuria. I am sure I have done so myself in several instances.

It may be asked what advantage there is in separating cylindroids from casts proper, as it is admitted that both are formed within the renal tubules, are composed of similar material, and are indicative of renal irritation. Despite these facts there is much and good reason for maintaining a distinction. Of course, in a strict sense, these structures are casts or moulds of the tubules, but their form and appearance, excepting in the few cases referred to, easily distinguish them from the ordinary cast, and their significance is entirely different. Just as there is a great clinical advantage in separating the

[1] Amer. Journ. of Med. Sci., January, 1893.

"albuminurias and Bright's disease of oxaluria and uric acid," which Da Costa speaks of, from ordinary chronic nephritis, in which the prognosis is so much more grave, there is an advantage in keeping the cylindroid, an indication of mild renal congestion and irritation, separated even in name from the nephritic cast, whose significance is more ominous.

If we could learn to feel that casts after all are not always an indication of serious renal mischief (as they undoubtedly occur in cases of transient renal congestion, icterus, and other conditions), it would be less necessary to retain the special name, "cylindroids." As far as the form of cylindroid that is almost or quite indistinguishable from ordinary casts is concerned, it is manifest from what has been said that there may be a regular succession of forms, from the marked and distinctive filamentous cylindroids up to such as are in reality true casts; but when the latter occur singly or in small number amidst numerous distinctive cylindroids, one cannot but view them with a considerable degree of composure. On the other hand, when hyaline casts appear in the urine in some number, without cylindroids, it would appear that the congestion or irritation producing them had been from the first more severe than such as ordinarily gives rise to cylindroids.

My conclusion is that cylindroids are formed in the renal tubules as a result of moderate renal congestion or irritation, that they may occur in albuminous or non-albuminous urine, and that they may be of such appearance as to be almost indistinguishable from ordinary casts, or may even be transformed into such.

CLINICAL MEMORANDA.

TWO CASES OF LABIAL CHANCRE IN CIGARMAKERS.

BY WILLIAM S. GOTTHEIL, M.D.,
ATTENDING SURGEON, DISEASES OF THE SKIN, NORTHWESTERN DISPENSARY, NEW YORK.

ATTENTION has been called of late in the European journals to the frequency of extra-genital infection with syphilis. It has long been known that such cases occur. Casenave recorded a number in the early decades of the century, and subsequent observers have added to the list. The mass of recorded instances is already too great to be collected. It seems very probable, however, that these unusual infections are even more numerous than was ever suspected. An increased familiarity with the early symptoms of the disease, and the inclusion of syphilography in the curriculum of our medical schools, have led to a more careful search for the seat of the initial lesion in apparently mysterious cases; with the result that such unexplained cases are becoming much more rare. No one now believes in the occurrence of syphilis without a chancre, though it may have been unnoticed by the patient. As a chancre has a definite life-duration of its own, though within rather wide limits, one situated within the urethra, within the rectum or within the vagina may readily escape the patient's notice, more especially as it is usually entirely painless. On the other hand, a chancre situated upon some portion of the body other than the genitals is liable to be mistaken for a furuncle or boil, or to be neglected entirely.

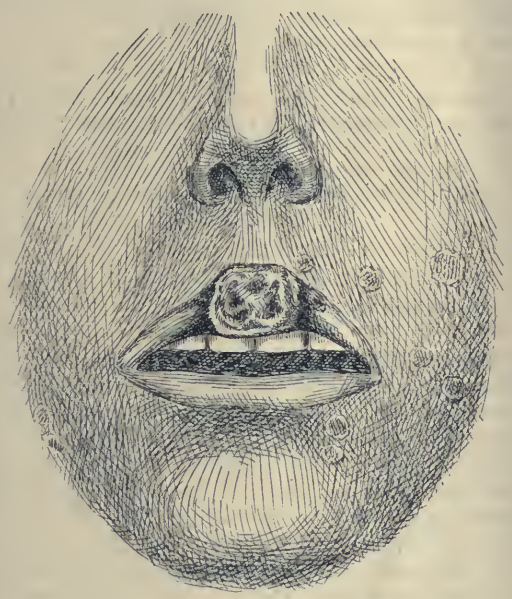
It must never be forgotten that a chancre and the subsequent syphilis constitute a venereal disease only by accident. The contagium will grow in any human body that has not already been infected by it. It can enter the body at any point where there is a break in skin or mucous membrane. It can be transferred from one subject to another without direct contact, by means of an object or person acting as intermediary. It is simply because during copulation individuals usually come into close and prolonged personal contact favorable for the transmission of a living, organic contagium that is in the blood, that most chancres are situated upon the genitals. If any other act of social life involved similar processes, chancres would be as common on the organs employed as it now is upon the penis. In certain regions, where peculiar customs prevail, we do indeed find this to be the case. Thus, long series of cases have been recorded in Russia, where the habits of the peasantry are not of the most cleanly or hygienic. A common domestic remedy in that country for certain affections of the eyes, such as furuncles, small abscesses, etc., consists in the sucking or licking the affected part by one of the patient's relatives or friends. This primitive therapeusis is in vogue with us only in the case of snake-bites, where it has a rational basis and some success. Snake-bites, however, are rare; nor do I know a single case in which the treatment has caused infection of any kind.

The common use of instruments that are taken into the mouth has caused many epidemics of syphilis. Notably was this the case among the French glass-blowers, so that governmental interference finally became necessary. The long tube used by a gang of men in common was not to be employed without an "embout" or mouthpiece, of which each workman was compelled to have his own; and heavy penalties were inflicted for a violation of the rule. The men accepted the innovation with enthusiasm at first, but they soon relapsed into their former and easier habits; and Chassagny, the inventor of the mouthpiece, records with a sigh the failure of his well-meant efforts.

In our own country, with more cleanly habits, such sources of infection are rarer. Yet they do occur, as the two cases that I am about to record will prove. The infective source is of the greater interest, as it directly

affects a very large portion of the community—the cigar-smokers.

A. McK., aged nineteen, born in the United States, and a cigar-finisher by occupation, came to me at the N. W. Dispensary on January 11, 1892. In the first week of December, 1891, she noticed a slight swelling of the upper lip. Soon a small lump appeared, which continued growing in size during the rest of that month and finally became as large as a small walnut. On January 1st she first noticed some blotches on the face and body; but these, she affirms, have entirely disappeared. She gives an indefinite history of a sore-throat early in December. She has grown thin and pale, and has lost strength and appetite.



The patient thinks her affection a trivial one, but would like to know why the lump on her lip does not disappear. Though she does not feel very well, she has not let it interfere with her work; she expected it to go away of itself. She claims that her intimate friend, who finishes cigars on the machine next to hers, had the same thing on her lip three months ago, and that it went away in a short time without medicine. She thinks she must have acquired it from her friend, as both drink tea from the same cup at lunch. She has had some little trouble about the genitalia, which she considered of no consequence.

The patient is a pale, anemic girl, undersized for her age, and rather stupid. On her upper lip, at about the middle line, is a lump as large as a hazelnut. It is cartilaginous to the touch, sharply limited, and entirely painless. Its external surface is occupied by an irregularly square, excoriated patch, the base of which is uneven, dark greenish-gray in color, and slightly secreting. It is a typical initial lesion, and from its location and prominence is noticeable at a considerable distance. A general macular syphiloderm is in full bloom upon her body, though slight upon the face. The characteristic adenopathy is well marked everywhere. She has a diffuse specific pharyngitis. The vagina contains moist papules, and there is a profuse vaginal discharge.

This, then, is the condition of a patient who claims to be fairly well, and who is merely tired of the disfigurement caused by the lump upon her lip.

The chief point of interest in the patient's history, however, is her occupation. Knowing something of the process of cigar-making, I questioned her closely in regard to it. That hand-made cigars are liable to be infected is a matter of common observation. Anyone who has watched the process cannot fail to have noticed the generally unclean condition of the workman's hands and table; but it is the finishing of the cigar that is most obnoxious. Most of the operators that I have seen use their saliva on the tips of their fingers to shape the ends of the cigars. A pot of paste stands on the table beside them, but it is quicker and easier to use the mouth. Besides this one and the same motion will suffice to cut off the redundant corner of the wrapper, and doing this with the teeth saves the trouble of taking up the knife again and cutting the point on the table.

I was not aware that the same thing was done with machine-made cigars, but the patient was quite frank when I questioned her about it. Machine-made cigars have to be finished in exactly the same way as the hand-made ones. The machine turns out the cigar unpointed, and the finisher completes the product by hand. She bites off the little triangular redundant piece of wrapper, and at the same time wets with her tongue the tip of the cigar, which is then moulded by hand. All the finishers that worked in the same shop as our patient did exactly the same thing. Paste-pots and knives were there, but it took too long to use them. The work was paid for by the piece, and could be done much more quickly in this way. Yes, she had heard something about the practice being forbidden, but no one did otherwise.

The patient's further history was unimportant. She was placed upon the usual treatment, and began to improve rapidly, both as regards the disease and as regards her general health. Both she and her mother, however, absolutely refused to believe in the seriousness and the contagious nature of her malady. She refused to stop work, and continued to make her cigars as before. I saw her some three or four times more, and then she withdrew from observation.

I had naturally been anxious to see her friend, from whom she supposes that she caught the disease; but I found it very difficult to do so. Finally, on February 3d, she came to the dispensary. Her history is as follows:

D. D., aged eighteen, born in the United States, in the beginning of October of last year first noticed a sore upon her lip. It began as a little pimple, but soon grew to the size of a nut. The girl gives a full and complete history of syphilis. There was a general macular eruption, general adenitis, defluvium capillorum, pharyngitis, etc. The sore on her lip disappeared spontaneously in a few weeks, and the girl did not then, nor does she now, attribute any importance to it or to any of the other symptoms. She works on the machine next to that of A. McK., whose intimate friend she is, and who sleeps with her. After much cross-questioning she admits having gone to a physician once when sick. He gave her a salve and some pills, but did not, she insists, tell her anything about the nature of her disease.

The patient is a tall, well-developed girl, of magnificent physique, and apparently in perfect health. A close examination, however, reveals the stains left by a former general macular eruption on the arms and chest. There are two large mucous patches upon the tongue. On the lower lip, a little to the left of the median line, is a small pea-sized, still indurated nodule, evidently the remains of the initial lesion. General adenitis is still perceptible, and there is a typical pharyngitis.

This girl worked all through her sickness, and is working still. She invariably finishes the tips of her cigars with saliva. She admits that the finishers have been told not to do so, but she says that the practice is universal. She was put upon the ordinary treatment, and improved whilst under observation. She laughed at the idea of having any general disease, and at the danger of contagion. She soon withdrew from observation.

Now here were two girls, in the early and most infective stages of syphilis, engaged in the manufacture of an article that is almost invariably taken into the mouth, and using their teeth and saliva to finish the very part of the article that comes in prolonged contact with the delicate and frequently abraded mucous membrane of the mouth. Every single cigar of the thousands that they must have finished in the last four months had carefully deposited upon it saliva that was admixed with the secretion from a chancre. When the sclerosis finally ran its course and disappeared, the secondary mucous patches, of much longer life and just as contagious, took its place. The necessary presence of acrid tobacco-juice in the mouths of these girls supplied exactly the conditions favorable for the continuance of the patches. Thus they will probably both continue to have an infective buccal mucosa during the entire active period of their syphilis. Their absolute disbelief in what was told them concerning the nature of their malady, and the certainty that they will not undergo the necessarily prolonged and careful treatment to be cured, render it probable that they will long remain in the contagious stage.

Meantime the cigars that they have finished have been scattered far and wide, to be smoked, in nine cases out of ten, without any protection in the shape of a holder between the tip of the cigar and the smoker's lips. I am well aware that tobacco is supposed to possess certain antiseptic qualities, but they are certainly not very marked, and we do not possess exact data as to their degree. We may hope for the best; but may not these infected cigars explain the origin of some of these mysterious labial, buccal, and tonsillar chancres that are seen; and, above all, may they not account for the very numerous cases of syphilis in which the inital lesion is not noticed at all, and the patient, though truthful, entirely fails to give any history of the beginnings of the disease?

The remedy for this particular source of infection is plain. The use of the lips and the saliva in the manufacture of cigars is a disgusting and filthy makeshift, and should be stringently prohibited. The Hygienic Section of the New York Academy of Medicine has, I am told, made some attempts in the past to put a stop to the practice, but their efforts have evidently been futile. Both patients affirm that the practice is universal in the large factory in which they work; and further inquiry has convinced me that the same state of affairs prevails in other factories and in smaller shops. Operatives will never of their own accord make a change that means decreased wages for them.

The employers, however, can be reached by law, and they can easily compel their operatives to use the paste-brush and the knife. There are State inspectors for these factories, and the local boards of health certainly have power. Each department and each floor of a factory is under the supervision of a foreman or superintendent, and no practice of the kind can be indulged in without his knowledge. A penalty of sufficient magnitude imposed upon the employer for every case of the kind would soon lead him to give stringent orders to his foremen, and without the connivance of these latter the practice could not continue.

25 WEST FIFTY-THIRD STREET.

A REPORT OF SOME FRACTURES TREATED WITH PLASTER-OF-PARIS SPLINTS.[1]

BY W. JOSEPH HEARN, M.D.,
SURGEON TO THE JEFFERSON COLLEGE HOSPITAL AND TO THE PHILADELPHIA HOSPITAL,

AND

J. P. MANN, M.D.,
INSTRUCTOR IN ORTHOPEDIC SURGERY IN THE JEFFERSON MEDICAL COLLEGE.

THE object of this paper is to direct attention to the utility of the plaster-of-Paris splint in the treatment of fractures. The fractures occurred in patients whose ages ranged from three days to seventy-eight years. To secure a successful result with a break at the upper third of the humerus, in a child at the tender age of three days, is, frequently, a most difficult task. Such a case was Baby H., a girl. This child, a patient of Dr. L. Jurist, sustained, during a trying instrumental delivery, a fracture at the upper third of the left humerus. Dr. Jurist employed the usual methods of management for such injuries, but could not maintain the fractured parts of the bone in apposition. Nursing, bathing, clothing, and interference by an incapable nurse all combined to frustrate the Doctor's efforts to effect a good result.

Two days after birth, with Dr. Jurist's assistance, a plaster-of-Paris splint was applied as follows: *a*, A plaster jacket, extending from just above the umbilicus (the cord not yet having fallen off) to the armpits, was put on; *b*, the arm, from the wrist almost to the seat of the fracture, was incased, the forearm being held nearly at a right angle with the arm; *c*, the third section commenced immediately above the point of fracture, extended well over the shoulder and was connected with the jacket by a few turns of the plaster bandage around both the left shoulder and the jacket. The case on the arm immobilized the elbow-joint, while that part above the break secured the shoulder from all movement except rotation. Extension was now made and the last section of the case was placed over the seat of the fracture, overlapping the parts of the splint on the arm above and below it. The entire arm was then secured to the trunk by several turns around the jacket. In

[1] Read before the J. M. DaCosta Medical Society of Philadelphia, Pa., January 13, 1893.

fourteen days the plaster case was removed. The fracture had united in good position and was now protected for two weeks more by three strips of board extending from the elbow to the shoulder, thus allowing gentle manipulation of the joints. The plaster case was applied over absorbent cotton, which protected the skin from irritation. There was no deformity or loss of motion.

CASE II.—A boy, William M., aged three years, fell and produced a "T" fracture of the right humerus. The arm was much swollen at the seat of fracture, and there was great difficulty in applying a splint in such a manner as to secure proper approximation of the broken ends of the bone without making too great pressure with the splint and bandage. It was, therefore, decided that a plaster-of-Paris case would give the most satisfactory result. The case was put on, over absorbent cotton, in three sections, the third section being placed over the seat of fracture and connecting with the sections on the forearm and arm. The section on the arm extended from just above the elbow-joint to the armpit. The splint was removed in three weeks. Inspection of the arm at that time, and again in ten days, showed that there was good union with no deformity, and that the "carrying function" of the arm was preserved.

CASE III.—W. O., aged twelve years, as the result of a fall, suffered a compound fracture of the right ulna and radius at their lower thirds. Some resection of both bones was necessary for satisfactory approximation of their ends. Extensive cellulitis, with profuse purulent discharges, set in within a few days. The pain occasioned by the frequent dressing of the wound as well as the likelihood of non-union of the bones, rendered it needful to immobilize the entire arm. A plaster-of-Paris case was put on in three sections, as in the preceding case, except that the third section covered the seat of fracture and was not over the elbow-joint. The proximal section began immediately above the break and extended over the elbow and up to the axilla, while the distal section covered the extended hand and fingers. Trap-doors were cut in the case, allowing the arm to be dressed without giving pain to the patient or disturbing the bones. The boy made an uneventful recovery, with good use of the arm. The case remained on ten weeks. It is but fair to state that the broken ends of the bones had been pushed into the dirt, rendering asepsis almost impossible.

CASE IV.—Mary W., aged four years, an idiot, suffered a fracture of the upper third of the left femur. She was unusually hard to manage, requiring constant watching to keep her and the dressings in place. Finding that she could not be controlled, a plaster case was applied. The distal section began at the toes and extended to a point just below the fracture. The proximal section began above the break and incased the entire trunk. While this section was hardening the child was on her right side and the upper third of the bone was held in proper position, as though the whole leg were straight and unbroken. With the child still on her right side, the middle section was now applied and the entire leg was immobilized in extension. The splint remained on eight weeks, giving good union, with but one-quarter inch of shortening, which may have existed prior to the fracture. The child soon learned to walk without any limp.

CASE V.—J. B., a boy, aged three years, an emigrant, had his right femur broken at its upper third, during a storm at sea. His mother, with five other children, was compelled to leave him in order that she might join her husband, who had gone West some months before. Ten days after the injury, a plaster splint was made, as in the preceding case, and in twelve weeks the boy was cured and sent home. In this case there was no shortening, but the right leg may have been longer than the left prior to the break.

CASE VI.—W. M., nineteen years old, suffered a fracture of his left femur, at its middle third. Extension and sand-bags were used. After eight weeks, union having taken place, he was allowed to get up on crutches, but did not use them, and within ten days his leg was badly bent outward at the seat of fracture. He was etherized and his leg and trunk were incased in a plaster splint as follows: From just above the fracture to the armpits a continuous splint was applied, along the left side of which a stout strip of board, about two and one-half inches wide and four feet long, was fastened by some additional turns of the bandage around the plaster jacket. The second section extended from the toes to the seat of fracture. When these sections had set, the leg was firmly pressed outward and the board was now fastened by plaster bandages to the leg part of the splint. Thus the board exerted a continuous outward leverage on the leg below the seat of fracture. In three weeks the man got up with a straight leg and had no further trouble.

CASE VII.—Mrs. S., a widow, aged seventy-eight years, fell down a flight of stairs and suffered a compound fracture of the left femur, three inches above the condyles. The wound and the surrounding parts were rendered aseptic and dressed with mercuric-chlorid gauze after a little aseptic iodoform had been sprinkled over the wound. The patient was then etherized and a plaster splint applied. One section extended from the toes to just below the fracture, and a second section began above the injured part and covered the leg and trunk. The third and last piece of the splint was put on over the wounded part, connecting the first and second sections. The woman was carefully watched for a rise of temperature, which was rather expected, but none occurring, the splint was not removed until the ninth week. Gentle motion and massage were now employed to restore the function of the joints. The woman is, at the time of this writing, entirely cured and can walk as well as she ever could. She had no pain to speak of, and travelled six hundred miles on the cars within three months after the reception of the injury.

To sum up: All of these plaster cases were put on over absorbent cotton, thereby guarding against undue pressure from swelling or upon bony prominences. There were no bedsores or excoriations in any case. The patient's position could be changed, and bathing was practised with little discomfort. The plaster splint does not require constant re-application or re-adjustment, as do most splints, for in these cases the splints were not removed until a cure had been effected. Plaster splints are cheap and durable. In fractures of the upper extremities, the patients, after a few days in non-septic cases, may walk around with perfect security when wearing a plaster-of-Paris dressing.

A CASE OF RHEUMATIC FEVER WITHOUT JOINT-SYMPTOMS.[1]

BY ISAAC HULL PLATT, M.D.,
OF LAKEWOOD, N. J.

THE case here reported possesses somewhat unusual interest, presenting, as it does, symptoms not belonging to any one particular fever, and running an anomalous course throughout.

The patient is a married woman of early middle life, whose general health is and has been good. She spent last summer in a private cottage in the hills of central New Hampshire, at an elevation of about twelve hundred feet, where the hygienic conditions are supposed to be unusually good. The only qualification to this statement is that at one time during the latter part of the summer the water in the well used by the family became rather low, owing to the drought, and acquired a faint odor, upon the discovery of which its use for drinking-purposes was discontinued.

Early in September, the patient was one of a driving party that made a tour through the southwestern part of Maine, which occupied about ten days. On her return she complained of an unusual degree of fatigue, and on the following day appeared very tired and listless. In the evening of the day following her return, the temperature was found to be 101.5°; on the following morning, 99.5°, and in the evening, 102°. For three days the temperature followed a curve of this character, with the morning remission, and by that time the evening temperature was about 103.5°. The temperature-curve, the season of the year, and the feeling of exhaustion during the prodromal stage suggested enteric fever, which might have been attributed either to the water from the well or to some possible but unknown exposure during the journey. On the fourth day, however, the fever suddenly abated, the patient rapidly rallied, and in a few days was about as well as ever, and able to make the necessary preparations for her return to her winter home in Lakewood.

She arrived on the first day of October, only moderately tired from her journey, but on the evening of the third, complained of a feeling of extreme exhaustion, and went to bed early in consequence. The temperature was then found to be 102.5°. On the following morning it was 100°, in the evening, 103°; then in the morning, 101°; evening, 103.7°; morning, 102.5°. It continued to rise in this manner for five days. During this period there were no marked symptoms beyond the peculiar course of the fever, and a feeling of great exhaustion, which, of course, again suggested enteric fever. The bowels were inclined to be loose, but there was no diarrhea. The urine was normal in quantity, strongly acid, and free from albumin. The medication during this period was in the way of intestinal antisepsis, on the assumption of enteric fever. On October 7th, Dr. Westbrook saw the patient in consultation, but we were unable at the time to make a diagnosis. During the following two days the temperature continued to mount, reaching a maximum of 104.8°. The cold pack was repeatedly applied, and brought down the temperature; but upon the removal of the cold, the temperature would immediately mount again, returning in a few minutes to its previous elevation. During the height of the fever the skin acted freely, and the urine continued acid. Quinine in ten-grain doses was repeatedly used, without any antipyretic effect whatever.

On October 9th, Dr. Westbrook saw the patient again, and discovered a very faint direct aortic murmur. This, with the perspiration and the acid condition of the urine, led him to suggest the possibility of rheumatic fever, with a mild endocarditis. There had not been, nor did there appear subsequently in the case, any pain, redness, or swelling of joints.

To test the question of diagnosis the cold packing was stopped, whereupon the temperature rose at once to 104.5°, at which stage twenty grains of sodium salicylate with sodium bicarbonate were given. An hour and forty minutes later the temperature was 102.7°, but in another two hours it had risen to 104.5°. The patient was then given regularly, every two hours, twenty grains of sodium salicylate with an equal amount of sodium bicarbonate. During the next twelve hours the temperature gradually fell to 101°, and in the subsequent twelve hours to normal. The sodium salicylate by this time having caused some gastric disturbance and mild cerebral symptoms, it was suspended, whereupon the temperature rose to 102.5°, but upon the resumption of the medicine the temperature promptly fell to normal. It never afterward went higher than 101°. The subsequent history of the case was that of convalescence, and on October 27th, six weeks after the appearance of the first symptoms, the patient was pronounced well. During the continuance of the fever, there were no joint-symptoms; but during the few weeks following there were occasional slight pains in some of the joints, and the acidity of the urine was quite persistent. During this time the patient was kept upon alkaline treatment, with good effect. Ever since the attack there have been occasional twinges of this kind, and also wandering pains about the chest. In December she was examined by Dr. Henry Conkling, of Brooklyn, who discovered evidences of slight pleuritic adhesions.

With the exception of these slight pains the woman has since been well. The heart was left undamaged. It should be noted, as perhaps having some bearing on the case, that she had had for some years previously a very slight synovitis of one of the knee-joints, occasionally producing a slight degree of lameness and always a little stiffness and crepitation. This had been attributed to a fall in mountain-climbing.

In a cursory examination of the literature of rheumatic fever, I have failed to find the record of an exactly similar case, or of any case entirely free from joint-inflammation, though cases are not rare in which the joint-symptoms did not make their appearance till some time after the fever had been established. I regret that I have not had the opportunity of making a fuller research into the reports. The acid condition of the system, as evidenced by the rather profuse and sour perspiration, and the acid urine; the aortic murmur, transient in character; the sudden rise of temperature after it had been brought down by cold applications, and above all, the prompt and thorough response to sodium salicylate, leave little if any doubt that the case was one of rheumatic fever, slightly affecting the endocardium and pleuræ, and leaving the joints free.

[1] Read before the Alumni Association of St. Mary's Hospital, Brooklyn, March 23, 1893.

Enteric fever was absolutely excluded by the latter part of the history of the case. To exclude an irregular form of malarial fever is, perhaps, more difficult, but the fever bore no resemblance to any well-known type of malaria, and it is highly improbable that a malarial fever should not be in the slightest degree affected by quinine and be subdued at once and completely by sodium salicylate. It is possible, of course, for endocarditis to occur without rheumatism, but its existence is highly suggestive of a rheumatic origin when no other cause can be found.

The possibility of intra-pelvic inflammation was disposed of by repeated careful examinations of the pelvic organs, and by the fact that the patient has never, before or since the attack, suffered from any trouble whatever connected with these organs, but in this respect is and always has been perfectly normal. That sodium salicylate is an antipyretic in other affections than rheumatism, I am not prepared to deny, though I have never found its action in such cases very marked or trustworthy, but that it should cause a complete dissipation of the fever and a cessation of all of the symptoms in a few hours, in any other condition than rheumatic fever, appears to me highly improbable, and opposed to the teachings of all my reading and experience.

MEDICAL PROGRESS.

The Toxin of Tetanus.—COURMONT and DOYEN (*Province Médicale*, March 18; *Rev. gén. de Méd. de Chir. et d'Obstet.*, No. 22, 1893, p. 169), as the result of a study of the pathogeny of tetanus, arrive at the conclusion that the bacillus of Nicolaier gives rise to the symptoms of tetanus through the intermediation of a soluble ferment which it generates. This ferment, which is not toxic *per se*, elaborates within the organism a substance of tetanizing properties, comparable in its effects to strychnine. This secondary substance may be found in the tetanized muscles, in the blood, and sometimes in the urine. It resists prolonged boiling, while the products of the tetanus bacillus are rendered innocuous by exposure to a temperature of 149°. Certain conditions of temperature seem essential to this reaction. This will explain the immunity of frogs to tetanus in winter-time. Immunity, natural or acquired, artificial immunization, may be considered the result of influences that prevent, retard, or arrest this process of fermentation. It is probable that other products of microbic activity, said to be toxic, act equally as ferments, producing toxic matters within the organism. It may be that the paralysis and other late accidents of diphtheria can be explained in a similar manner.

Cornet-player's Cramp.—TURNER (*Lancet*, No. 3635, p. 995) has reported the case of a man, twenty-nine years old, who had played the cornet as a means of livelihood from the age of nine years. For two years he had observed that he was unable to sound certain notes, from an inability to direct the tongue for that purpose. These movements could, however, be performed readily and easily when the man was in his own room, practising, or when allowed his own time, but not when suddenly called upon to do so. After playing for some time, the condition seemed to improve rather than become worse. In all other actions, both in playing the cornet and otherwise, the movements of the tongue were uninterfered with. At no time was any pain felt. The tongue was large, atonic, and somewhat indented by the teeth, but this condition improved under treatment with strychnine and dilute hydrochloric acid. Toward the tip a few fibrillary contractions could be seen. The electric reactions were normal. There was no affection of the lips or soft palate, and the linguals and labials were well formed. The knee-jerks were equal and of normal force. There was no family history of neuroses. It was not known that other cornetists suffered similarly.

Congenital Absence of the Pectoralis Major and Minor.—ZIMMERMANN (*Corr.-bl. für Schweizer Aerzte*, No. 10, 1893, p. 358) has reported the case of a man, without family peculiarity, in whom the pectoralis major and minor and the mammary gland upon the right side were wanting, and the serratus magnus was diminutive. The right nipple was lower than the left, and its pigmentation, and that of its areola, was less than on the opposite side. The growth of hair and the deposit of fat were also deficient on the right side. The axilla upon the left was well defined. On the right the anterior margin of the axilla was constituted by a peculiar fold of skin, stretched between the arm and the chest and extending down to the elbow, which conveyed the sensation not of a simple duplicature of the skin, but of a tendinous band. The function of the arm and shoulder were, however, not appreciably interfered with. The entire upper extremity, excepting the muscles of the shoulder, was somewhat less well developed than the left. In diagnosis the juvenile type of muscular atrophy of Erb and anterior poliomyelitis were excluded. But two other cases of the same kind were found in the literature.

Spontaneous Rupture of the Symphysis Pabis During Labor.—OELSCHLÄGER (*Centralbl. für Gynäkol.*, 1893, No. 24, p. 563) has reported the case of a primipara, twenty years old, in which with the onset of labor-pains two eclamptic attacks occurred in quick succession. The lower extremities were edematous, and the urine contained a small amount of albumin. The promontory of the sacrum could be touched with two fingers introduced into the vagina. The head was quite high in the pelvis and but slowly followed in the grasp of the forceps, a not excessive degree of traction being exercised. As the head began to rotate in the small pelvis a crack was distinctly heard. Examination disclosed a separation of 1.15 inches in the situation of the symphysis pubis, and the delivery of a living child weighing nine pounds was soon readily effected. On the day following the labor a leather support was applied to the hips. For two weeks the region of the symphysis was tender upon touch and painful upon movement, but a week later the woman was able to be up and about, although a slight degree of separation of the pubic bones persisted.

The Relation of Age, Sex, and Social Condition to the Mortality from Tuberculous Disease.—In an analysis of 1771 fatal cases of tuberculous disease in the Swedish-Finnish community of Helsingfors during the years from 1882

to 1889, HOLSTI (*Zeitschrift für klinische Medicin*, Bd. xxii, Hefte iv u. v, p. 317) found that the mortality from this cause was incomparably greatest during the first two years of life, but declined thereafter, to reach its minimum between the years of five and fifteen; rising again, to reach its maximum between the years of thirty-one and forty, after which it again gradually declined. In general, the mortality from tuberculosis was greater among males than among females, except between the fifth and the twentieth year, during which period the greater number of deaths from tuberculosis occurred among females. After the maximum mortality had been reached, between the thirty-first and the fortieth year, the mortality among females gradually grew less; in males, however, the mortality continued at almost an unchanged level until the age of sixty.

Trephining for Cerebral Softening.—LANPHEAR (*University Medical Magazine*, July, 1893, p. 785) recommends trephining of the skull in cases of cerebral softening as a result of hemorrhage, embolism, or thrombosis, for the relief of such symptoms as mental irritability and mental aberration. He reports an illustrative case in a man of fifty-six who had been right hemiplegic and aphasic for six years as a result of cerebral hemorrhage. After the skull was opened and the dura turned back "fully a pint of broken-down brain and other debris of creamy consistence" was evacuated. The large cavity was carefully washed out with a sterilized solution, some of which was permitted to remain, and the wound was closed and an antiseptic dressing applied. There was no change in the palsy or the aphasia, but the mental condition was decidedly and permanently improved.

Influence of Faradism upon Irritability of Muscle and Nerve.—From a study of the behavior of muscles and nerves to the stimulus of the faradic current, MANN (*Deutsche Archiv für klin. Medicin*, B. v, H. 2 u. 3, p. 127) has found that the application for several minutes to a muscle or nerve of very weak currents, whose intensity is lower below the minimum necessary to induce contraction, is followed by no change in faradic irritability. Stronger currents that induce muscular contraction cause diminution of irritability in a degree in direct ratio to the intensity of the current and the duration of its application, it matters not whether the muscle be stimulated directly or through its nerve. Faradization repeated regularly for several days gives rise to an increase in the irritability of the faradized muscle or nerve.

Tumor of a Cerebral Peduncle, with Unilateral Tremor.—At a recent meeting of the Société de Biologie, BLOCQ and MARINESCO (*Le Mercredi Médical*, 1893, No. 22, p. 269) reported a case which during life presented left-sided tremor indistinguishable, graphically or clinically, from the tremor of paralysis agitans. Death took place from pulmonary tuberculosis, and at the autopsy a tubercle as large as an olive was found in the midst of the right crus cerebri. The tumor occupied a large portion of the locus niger, and, notwithstanding its volume, did not involve the crusta, the superior cerebellar peduncle, or the fibers of the oculo-motor nerve. There was neither ascending nor descending degeneration. In explanation of the tremor, irritation of the pyramidal fibers is suggested.

THERAPEUTIC NOTES.

Poisoning with Turpentine.—CARVETH (*Canadian Practitioner*, June, 1893, p. 429) has reported the case of a woman who, at bedtime, took about half an ounce of old spirit of turpentine mixed with an ounce of whiskey, in mistake for castor oil. The mistake was only noticed after the turpentine had been swallowed, but nothing was done at the time except to take a dose of castor oil. The patient shortly afterward fell asleep, but was awakened in the course of five hours with sickness of stomach. A little later she vomited, and after the lapse of several hours more she had a convulsion, followed by loss of consciousness. The pulse was weak, feeble, rapid; the face and lips pale; the patient restless, at times delirious and talking incoherently, but capable of being partly roused. Urine had been passed in generous quantity. Whiskey, spirit of nitrous ether, milk, and sweet oil were given, and warmth was applied to the body. Vomiting was induced by irritating the fauces. The vomited matters had a strong odor of turpentine ten hours after the fluid had been taken. After free vomiting, consciousness was regained and complaint was made of a burning pain in the right leg. Examination disclosed the presence upon the posterior aspect of the knee of a blister 5 by 13 inches in extent, the contents of which were watery and emitted an odor of turpentine. Gangrene of the superficial parts took place in this area, and fifteen weeks elapsed before the resulting ulcer healed.

Myxedema in an Insane Woman Successfully Treated by Means of Thyroid-feeding.—ALEXANDER (*Medical Chronicle*, vol. xviii, No. 3, p. 175) has reported the case of a woman, forty-one years old, who had been insane for seven years, and who had presented symptoms of myxedema for two years. The mental condition had become one of chronic mania, with considerable dementia. Treatment by means of thyroid-feeding was instituted, half a minced gland from a cow, mixed with bread-crumbs, being given twice weekly. The administration of the glands was followed by nausea, but emesis occurred on only one occasion. A marked improvement in the patient's physical condition was at once apparent, and continued until the manifestations of myxedema had disappeared. In the course of the treatment the woman became quieter, and fairly rational at times, but this improvement did not continue.

Sodium Phosphate for Trigeminal Neuralgia.—In a rebellious case of trigeminal neuralgia, in which all of the usual therapeutic resources had been exhausted without affording relief, GLOVIEUX, of Brussels, tentatively practised subcutaneous injections of sodium phosphate, and with admirable results. The patient, who had suffered for two years, was completely relieved. Ten other cases of trigeminal neuralgia were treated similarly, with success in seven. A solution of thirty grains of sodium phosphate in three ounces of distilled cherry-laurel water was prepared, and of this from fifteen to forty-five minims were injected daily.—*La Semaine Méd.*, 1893, No. 33.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 15, 1893.

MEDICINE AT THE COLUMBIAN EXPOSITION.

ON the interior of the great dome of the Administration Building of the Columbian Exposition, at Chicago, hang eight bronze tablets commemorative of the eight events that most contributed to make our present civilization possible. One bears the name NEWTON, one COPERNICUS, names connected with the establishment of the principle of inflexible law and order in inorganic nature. One tablet celebrates the introduction of gunpowder, one the discovery of printing; one bears the name WATT and the date of the invention of the steam-engine, one the name MORSE—to whom is due our present system of rapid transportation and communication.

But perhaps no physician will fail to see the significance in promoting our present economic condition of the event celebrated by the tablet on the north wall:

> JENNER
>
> DISCOVERED THE PRINCIPLES OF
>
> VACCINATION IN 1796.

Europe might have thrown aside fatalism and superstition and become imbued with the idea of the stability and inviolability of Nature's laws; she might have printed books and papers; she might have obliterated feudalism with gunpowder and travelled by steam controlled by the electric telegraph;—nevertheless, without that security that vaccination has furnished from a pestilence we know now only by name, the industry and the wealth of to-day would be impossible. It is, perhaps, worthy reflection that nothing so much threatens the usefulness of this great exhibition as the possibility of an epidemic of Asiatic cholera, and to prevent such an epidemic we have only the uncertainty of quarantine.

Every physician who visits the Exposition and notices the fact that there is no combined medical exhibit will regret the lack of organization or lack of spirit that has allowed this great opportunity of advancing our professional interests to slip by unimproved. In the World's Congresses that are held in the Art Institute, a place was assigned to medicine, but it was not filled. It cannot be urged that the meeting of the American Medical Association and the Pan-American Congress, or the World's Congress at Rome, fills the place that the management of the Exposition proposed.

The hospital service for such emergency cases as the erection of the buildings for the Exposition naturally required has been improved and extended for the emergency work that now comes with the throngs of visitors. The emergency hospital is under the supervision of a medical director and a staff of thoroughly equipped physicians, every one of whom has had hospital service, most of them in the Cook County Hospital.. The hospital itself, though not an exhibition, is well worth the attention of medical visitors, and medical men will be received without formality. The equipment and furnishings are good, and the nursing is a fair representation of the nursing of the best hospitals in the country. The ambulance department is well manned, under the direction of a physician who has been thoroughly trained in the theory and practice of rendering first aid to the injured. Unfortunately the ambulances are of an antique, delivery-wagon pattern, similar to those that are being worn out none too fast in all of our large cities. Their inadequacy has lately been tested in an accident that threw upon the ambulance service the transportation to the hospital of fifteen or twenty injured painters and decorators.

Perhaps the most illustrative medical exhibit, and one that is well worth a protracted study, is that of the United States Army in the model hospital

just south of the United States Government Building. The first floor of this hospital is fitted out with a drug-room, a supply-room, and an office, and the ward itself contains a single model bed. The remainder of the room is filled with an exhibit from the United States Army Museum at Washington. It will require a considerable amount of time to properly study this exhibit, and, as there is usually a very great crowd in the rooms, physicians are advised to visit them early in the day. On the second floor of this hospital is a clinical laboratory in working order. A modest notice upon the stairway excludes all visitors except members of the medical profession; but anybody who chooses can go into the laboratory without a pass or without formality. A polite attendant will answer all questions that are asked in relation to the working of the laboratory, and a careful study may be made of this laboratory by making application for the opportunity from the officer in charge.

In the south end of the gallery of the Liberal Arts Building, the colleges and universities have their exhibit. The medical man will find much to admire in the exhibit of the Johns Hopkins University. The alcove in which this exhibit is placed is a good resting-place after a long tramp. All of the publications of the University are on tables and can be consulted. There are a few interesting exhibits from the medical departments of Harvard University, the University of Michigan, the University of Pennsylvania, and Columbia College; but we regret that the same spirit has not been manifested in the exhibits of the medical departments of these Universities as is to be seen in the exhibits of other departments of the same institutions. The veterinary department of the University of Pennsylvania has a very much more instructive and attractive exhibit than the medical department itself. In none of these exhibits is to be found a display of the work of medical students, and in fact nothing that shows the character or quality of medical education. From the standpoint of a medical teacher, there is no exhibit from these schools worthy the names and reputations these institutions carry.

The most instructive exhibit of the science of medicine is that of the twenty-one German universities. This display is to be found in the second and third galleries of the German section of the Liberal Arts Building. The German educational exhibit is shut off from the general public, and the medical visitor can have an opportunity of studying it only by giving his card to one of the German Imperial Guards, who patrol the exhibit, and requesting him to take it to the commissioner in charge. In this way an escort can be secured and every opportunity to study the marvellous exhibit that these universities have made. This exhibit is particularly rich in the department of medicine. It includes not only a careful study of the educational methods and curricula of the medical schools, but also a full account and fair exhibition of the material equipment of some of these universities. The equipment and material for anatomic study, including histology, is elaborately laid out in one section showing all of the instruments, manikins, preparations, microtomes, and microscopes used in this department, not only at the present time, but in past years. In the department of bacteriology, living and growing specimens are to be observed from day to day, mounted with special reference for exhibition and demonstration to classes. All of the necessary equipment for this department is also in working order, manufactured in various styles and arranged in the best manner for exhibition. The operating surgeon and gynecologist will also see the identical furniture and equipment of the best operating rooms in Germany, with photographs and plans of hospitals. The pathologic department is, as we should expect, very rich. The specimens are well described in a catalogue, which will be furnished the student on application. Although other exhibits are much more brilliant and, upon the first view, more attractive, the bibliographic exhibit is perhaps the richest of all of the exhibits of the German universities. In medicine this exhibit is naturally very large and choice, and will well repay a careful and critical study, in spite of the fact that the three or four great libraries of the United States possess much of it on their shelves. Such universities and colleges as are entitled to this consideration may, during the progress of the Exposition or soon afterward, receive a handsomely printed account of the exhibition of the German universities prepared especially for this occasion. This series of handsome quarto volumes, of which but one volume has appeared, will be a lasting monument of this splendid educational work that Germany has so well accomplished.

In the gallery of the Liberal Arts Building the camp-followers of medicine have made grand exhibitions, which will attract much attention. Every-

one will be interested in the exhibition of the manufactures of optical, chemical, and physical instruments. These exhibitions will be found in the departments of the various foreign countries and in the north gallery of the Liberal Arts Building. The exhibition of the Swiss instrument-makers is, however, on the first floor in the Swiss section. Pills, powders, surgical instruments, and office appliances are elaborately exhibited in this gallery.

All appliances relative to public and domestic hygiene, to charities, correction, and reformatory institutions, are exhibited in the south end of the Ethnological Building. Here are to be found the exhibits of the principal hospitals. Special attention should be given to the exhibits of the Johns Hopkins Hospital and the Boston City Hospital. Much valuable information for the hospital man will be obtained from these exhibits, and hospital wardens and managers will here find a great many valuable hints in hospital management and equipment.

The State Board of Health of Massachusetts has made one of the most attractive and instructive exhibits, and here the physician will receive valuable help in his study from the courteous attendants, all of them officers of the Board. This valuable exhibit is one of the most suggestive in the line of life-saving. A study of the work of the various charitable and reformatory institutions, whose attractive exhibits fill much of this building, is urged upon all physicians, whether their interest has been already aroused by practical study of these subjects or not. Attention is called to the exhibit of the Philadelphia Children's Aid Society, which has done such marvellous work in providing country homes for destitute children, and thus not only added much to life and happiness, but aroused alarm and consternation in the ranks of professional charity-mongers.

QUARANTINE CHANGES.

WITH the stroke of midnight on June 30th, the power of the Philadelphia Board of Health over maritime quarantine was terminated by law. This power has been exercised for almost a century. The present law, which takes the form of a supplement to the act of 1818, would fill several pages of THE NEWS, and represents substantially three influences. The agitation was begun several years ago by residents and property-owners in the neighborhood of the present quarantine-station to secure its removal. This influence was insufficient alone, but the continual disputes between the shipping interests and the local Board of Health last summer led to an effort on the part of the former to restrict this local control over quarantine. Then the developing sentiment in favor of National quarantine was accepted by both of the interests named as a satisfactory solution of the difficulty, and consequently the present law exhibits clearly concessions to all three views. The removal of the Lazaretto from Tinicum township must occur not later than July 1, 1895, and the conditions under which a new station is to be located are so hedged that it will be impossible to select any spot on the mainland of Pennsylvania. The control of quarantine-management is given to a board of seven persons, the exact function of which will only be shown by experience. In the constitution of this board, two non-official bodies, the College of Physicians of Philadelphia and the Maritime Exchange, have a voice, each appointing a member. It is probable that the bill could not have been passed without this concession to the latter organization; yet in spite of the respect due these two bodies, one eminently honorable in professional aspect and the other eminently representative of the business community, the policy of allowing public office to be filled by them is open to discussion.

While the bill, perhaps, creates a sinecure position, in that it gives the Quarantine Physician such liberal assistance that he is practically relieved of actual boarding-duty, it is to be commended for abolishing the double-headed system by which the Port Physician and the Lazaretto Physician took turns, so to speak, at the duties. The useless office of Quarantine Master is also abolished, as is also all payment of fees to the officials, a reform that is highly commendable.

The most important feature of the bill, however, and one that does not seem to have attracted much attention, is the provision made for the substitution of National for State quarantine. It is, we believe, the first act of State legislation, at least in the eastern United States, that provides definitely for this reform. The act empowers the Govenor to suspend the whole State system whenever he is satisfied that an efficient quarantine is maintained by the Federal authorities. That such a quarantine will before long be maintained, if it is not already, cannot be doubted, and it will be a notable reform when a single service uniform throughout all ports is established.

It is not unlikely that at the next session, the Legislature will see its way clear to a complete abolition of all maritime quarantine laws, and the relegation of the State and city health-authorities to their more appropriate functions of supervising local sanitary conditions. The National Government is abundantly able to take care of a maritime inspection.

PULSATING PLEURAL EFFUSIONS.

To MACDONNELL is due the credit of having, in 1844, for the first time directed the attention of the profession to pulsation as an occasional phenomenon in pleural effusions. A diligent search has discovered in medical literature only two cases reported prior to that date: the first of these was that of BAILLOU, published in 1640; the second that of PELLETAN, published in 1810.

WILSON and ESHNER (see p. 57 *et seq.*) have been able to collect up to the present time only sixty-eight cases, of which three occurred in the course of four years in the hospital services of the former. In fact, only one single observer, COMBY, who reports four cases, has seen a greater number. MACDONNELL, CHVOSTEK, RUMMO, and LIGHT have each reported three cases. Of the sixty-eight recorded cases, nineteen have come under the observation of six observers. These statistics warrant the belief that pulsation as a phenomenon in pleural effusions is far more common than is indicated by the number of cases placed upon record.

To encounter a case of this kind appears to increase the probability that the observer will encounter other cases anon. The explanation of this fact may lie in the law frequently commented upon by hospital physicians and surgeons, that curious and unusual cases are likely to run in series, or, and this is more probable, in the fact that the study of a condition at once so curious and so rare as the pulsation of a pleural effusion places the clinician keenly upon the alert for the recognition of new cases of the same kind; yet the phenomenon is so striking that it is difficult to understand how it could be overlooked in any ordinarily careful clinical examination.

This condition is clinically important as leading to closer study of the mechanical factors in pleural effusion and as furnishing a striking example of an unsolved problem in clinical pathology, for no one of the theories hitherto advanced, nor all of them together, as PROFESSOR WILSON has pointed out, are adequate to explain the occurrence of pulsation in certain rare instances of pleural effusion, and its absence in by far the greater majority of such cases.

EDITORIAL COMMENTS.

Syringomyelia and Leprosy.—The recognition of syringomyelia as a distinct clinical entity is of quite recent date. The commonly accepted view of its pathology is that the lesions depend upon a primary defect of development, owing to imperfect union of the lateral halves of which the spinal cord is constituted, with the formation of a condition known as gliomatosis, in sequence upon which, as a result of degenerative processes, cavities are formed in the spinal cord. The symptoms naturally vary somewhat with the situation of the lesions, which are, however, most common and most extensive in the cervical region of the cord. The symptom-complex described a number of years ago by Morvan, a French provincial physician, and known by his name, presents some features that suggest a relation with syringomyelia, and has actually been designated syringomyelia of Morvan type. Our knowledge of the morbid anatomy of Morvan's disease is, however, not sufficient to permit of an ultimate acceptation of this view. More recently an effort has been made to show that Morvan's disease and syringomyelia are but masked forms of leprosy, and it must be admitted that the two types of disease present certain superficial points of resemblance, as well as certain points of difference. As matters stand at present, and in the absence of conclusive evidence to the contrary, the three affections must be considered as distinct. In confirmation of this position, PITRES and SABRAZES (*Archives Cliniques de Bordeaux*, 1893, p. 232, No. 5) have reported three cases of syringomyelia, in one of which examination of a portion of nerve excised from the affected part, and in the other two post-mortem examination of sections of the spinal cord, failed to disclose the presence of the bacilli of leprosy. As negative evidence this can have but relative value. Taken, however, with the other facts in the case, it will go far to strengthen the prevalent view of the disease and its congeners.

Work and Rest.—In New York there lately retired from active duty a veteran editor who, in leaving his post, remarked that for forty-four years he had worked incessantly—without a single vacation. Physicians are accustomed to think of themselves as the hardest working men of the community, and this, so far as an equally large body of men is concerned, is certainly true. But there are few that can rival the service of the New York editor. A great physician of Philadelphia kept every office-hour for ten years. The peculiarity of the physician's work is that, like woman's, it is never done. The editor, the lawyer, can also have regularity in their lives, and when the day's labor is done, it may be more or less shut out of thought. Not so the doctor; the conscientious one, at least, cannot shut himself away from his patient, and the haunting sense of responsibility is always present, often like an incubus. Then, too, the enormous progressiveness of his science rouses the

ceaseless attention and keeps the energies alert in order to be abreast of the advances made every day. But it was our purpose to say that the New York editor, and those physicians who, like him, never take a vacation, are wrong. Better results would be attained with the rest than without it. It is useless to urge this truth on professional attention; useless, because every physician knows it—and ignores it! Lawyers can take care of their own property, as well as that of their clients, but as regards their own health, physicians are the most foolish of men. In accordance with the therapeutist's absurd practice, THE NEWS (which never rests) advises its readers to "throw physic to the dogs," and to take a month or two of rest each year. All need not go at the same time, so the public need not suffer. The railway and steamship have put all climates within a few days' reach.

Medicine and Art.—It seems worthy of comment that among the thousands of pictures at the Columbian Exposition, illustrative of the art and customs and types of every country and calling of the world, there are not half-a-dozen pertaining to medicine. The query arises, Is this because of any inherent qualities of medical ideals and practices that do not lend themselves to esthetic treatment? Every aspect of life, death, suffering, and wrong that the world has known is portrayed by the painter or sculptor, all save the one aspect of illness and the medical saving of life. The heroism of the men who kill is found pleasing, but not the heroism of those who bring life out of death. Perhaps this illogicality rests upon the larger one of the contemptuous and contemptible opinion of medicine in the minds of the world. Inexplicably, unconsciously, but also inevitably, the worldling rates the great physician immeasurably below the great general, statesman, or lawyer, and with the large majority there even arises a tinge or a downright dyeing of disrespect, when medicine comes into thought. As to the pictures again, the impracticability of the art-treatment of medical subjects is sadly illustrated by the examples at Chicago. Seligmann's "Billroth's Clinic" is well known to many through a cheap reproduction. Lessing's "The Sick Bed," and Jimenez's "Salle d'Hôpital, are hardly worth passing notice, and the treatrical clap-trap of Heyl's "Before the Section" (*sic*) is wholly execrable. All are simply prosaic recitals, none being touched with the divine fire of art. Are such things necessities or misfortunes—errors of the artist or inherent in the subject?

Scientific Sanitation in the Croton Watershed.—As a sample of the kind of intelligence and sanitation to be expected of politicians, Dr. Roosevelt found that because a cesspool drained into a running stream of Mount Kisco, the stream itself was ordered closed or dammed, with no provision whatever for the water to escape. The result would have been, first, a flooding of the cellars of the houses in the village with the sewage, and when the laws of gravitation could no longer be withstood, a breaking of the infected floods and general contamination. The closing of the cesspool, and the laws of hydrodynamics, never occurred to the wonderful Daly.

After an examination of the Croton watershed and the "sanitary" measures lately instituted there, Dr. Roosevelt thus concludes his report to the Academy of Medicine: "As matters stand now the people of New York are without any efficient protection against polluted water; and in this State we are compelled to face a summer which may bring cholera to our shores, and which certainly will close with the regular autumn outbreak of typhoid fever. The responsibility for our defencelessness rests with those who refused to permit the enactment of sensible laws."

A Commendable Departure.—In view of the recognized difficulty that sometimes attends the diagnosis of diphtheria and its discrimination from other similar or allied diseases, and of the direful consequences that may attend error in diagnosis, the action of the Board of Health of the city of New York in offering to make a bacteriologic examination in doubtful or suspicious cases, must be commended as a wise and progressive departure. The Board has designated a number of conveniently situated depositories, including its own laboratory, in whose care it has placed culture-tubes, which (with printed instructions) may be obtained and inoculated by the physician himself or, if he desire, by an official of the Board and again returned. The tubes are collected daily, and reports issued within twenty-four hours. The principle of application was already enunciated last fall in both this city and New York in connection with the bacteriologic examination of the stools of cholera-suspects. It marks a new era in the usefulness of Boards of Health, and is worthy of extension and universal adoption.

Kyphosis Bicyclistarum.—Every one has noticed, and many have wondered at the stooping posture of the bicycle-rider. The question aroused in the mind of the physician by this posture is whether "cycling" is a very praiseworthy method of athletics if it result in such contraction of the chest and unnatural bending of the spinal column. It would also appear that the muscles of the leg and hip are over-exercised, while those of the trunk and arms are left unexercised. A permanent posterior dorsal curvature has been noticed in many riders, and this has been given a distinctive name—*Kyphosis Bicyclistarum*—a name that of itself should be a warning to the enthusiast, even if the fact have no terrors. Those who are not deterred either by the name or by the possible deformity, and especially if young, and while the shape and structure of the spinal column have not been fixed by adult age, should correct the tendency toward improper curvature by complementary and counteracting forms of exercise.

Progress in Medical Education.—President Eliot, of Harvard University, in his speech to the alumni on commencement day, announced that the Law School had raised its standard by requiring, after the year 1896, the degree of A.B., S.B., or Ph.B., as a prerequisite for admission to its courses. There is already such a requirement in the Divinity School; and President Eliot expressed the hope that hereafter it would be adopted for the medical school.

But why should there be only the expression of a hope? Why should medicine lag behind other professions, in elevating the standard of entrance and of education? And why should the United States be behind every

other civilized country in this matter? Simply the power and the selfishness of proprietary medical schools. Nothing else!

Suicides in France, with an almost stationary population, have increased more than 21 per cent. in ten years. In 1891 there were 8120, in 1881 only 6751. The difficulty in getting poison, on account of stringency of the laws, has thus not prevented suicide, but has made more violent methods customary. Over 3000 killed themselves by hanging, and over 2000 by drowning, whilst there were only 183 by poison.

A Porter's Foot-race.—Jean Labasse, a French porter, recently carried a bag of sand weighing 220 pounds a distance of nineteen miles in fourteen hours, beating his competitors by several hours' time.

REVIEWS.

A STUDY OF THE ARTEFACTS OF THE NERVOUS SYSTEM. By IRA VAN GIESON, M.D. New York: D. Appleton & Co., 1892. (Reprinted from the New York Medical Journal.)

THE author has made a careful study of the changes, both gross and minute, produced in the spinal cord by injury during its removal from the body, and in its prepartion for microscopic study. He has compared the lesions produced by bruises with the conditions found in the thirty-one reported cases of malformation of the cord, excluding, of course, monstrosities, and concludes that but six of them are instances of genuine heterotopia. In the remaining twenty-five cases he claims that the lesions were caused by disease, post-mortem bruises, or both. It is noteworthy that the genuine cases were those early reported. The lesions artificially produced are reduplications of the gray matter, irregularly-shaped horns, canals, cyst-like spaces, and misplaced gray matter. They can be distinguished from true heterotopia by making serial sections, when it will be found that they are caused by areas of tissue having been forced upward or downward to other levels. The paper is admirably illustrated It should be read by all interested in the pathology of the nervous system.

HANDBOOK OF THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE THROAT, NOSE, AND NASO-PHARYNX. By CARL SEILER, M.D., Instructor in Laryngology, and Lecturer on Diseases of the Upper Air-passages, in the University of Pennsylvania, etc. Fourth edition, thoroughly revised and greatly enlarged. Illustrated with two lithographic plates, containing ten figures, and 107 engravings. 12mo, pp. 414. Philadelphia: Lea Brothers & Co., 1893.

THE mere fact that this work has reached a fourth edition is sufficient evidence that it fills a want long felt by "average general practitioners." As a book of quick, ready reference it has no rival in the field of laryngology, and the directions are usually such as to be readily carried out, even by comparative tyros in the work. The seeker after an exposition of the best and newest facts from the standpoint of the specialist, will, however, meet with disappointment, the book dealing rather with the pathology and therapeutics of several years ago than with those of the present. The first five chapters deal with the anatomy, physiology, and methods of examination of the upper respiratory tract, and are most clear and practical, and are also excellently illustrated. The remaining fourteen sections treat of the various diseases of the larynx, pharynx, and nose, and give a fair outline of the general principles of pathology and treatment.

Hypertrophic Catarrh is quite fully discussed, and this chapter is the best in the book; Atrophic Rhinitis, on the other hand, is one of the worst, hardly any of the newer methods of treatment being given, and the old and unscientific nitrate of silver formula of Bresgen being still lauded. Adenoid Growths of the Pharyngeal Vault are disposed of in little over a page, and the treatment suggested is hardly a safe one to trust to unskilled hands.

This edition will probably be eagerly welcomed by those for whom it was written, and will be a useful addition to libraries of students and general practitioners.

CHOLERA. By G. ARCHIE STOCKWELL, M.D., F.R.S. In two volumes. The Physician's Leisure Library. Detroit: Geo. S. Davis, 1893.

ONE arises from a reading of these two volumes with a sense of commiseration for their author, from a feeling of consideration that one is taught to hold for the senile, no matter how silly or absurd their word or act. It only seems remarkable that such a work as this should find issue in the last decade of the nineteenth century. Doctor Stockwell has added nothing to our knowledge, while his presentation of antiquated and exploded notions and his attack on current doctrines can have no influence upon the tendency of modern thought. He starts out with the view that the symptoms of cholera are dependent upon intoxication, the effects of which are especially expended upon the nervous system. He frankly confesses ignorance of the cause of the disease, denying the pathogenicity of the cholera-bacillus of Koch, and would direct his treatment to the control of the symptoms. In evidence of the character and spirit of the work, we shall make several quotations. Thus, in speaking of the parallelism between malaria and cholera, he makes the astounding statement that "The contracted vessels of the skin and the rigors associated with the cold stage in malaria are evidences of hypertrophy and hyperesthesia of vasomotor nerves." Pasteur, to whom the whole scientific world recently, on his seventieth birthday, paid homage, he characterizes as a "visionary, whose utterances have never been worthy of dependence, who is utterly devoid of physiological or other medical knowledge, and who, moreover, is not even a reputable chemist." Dr. Shakespeare's report on Cholera, presented, as special Commissioner, to the Government of the United States, he says "was compiled by an ardent bacteriologist, who, while gathering everything favorable to his view, carefully excluded all evidence calculated to invalidate." We have but to add that the book is calculated only to do harm, and that it is sedulously to be left alone.

International Clinics: A Quarterly of Clinical Lectures on Medicine, Neurology, Pediatrics, Surgery, Genito-urinary Surgery, Gynecology, Ophthalmology, Laryngology, Otology, and Dermatology. By John M. Keating, M.D., LL.D., Judson Daland, M.D., J. Mitchell Bruce, M.D., F.R.C.P., David W. Finlay, M.D., F.R.C.P. Volume I. Third Series. 1893. Philadelphia: J. B. Lippincott Company, 1893.

This valuable publication opens the third year of its existence with a remarkable and varied array of practical and interesting articles. Within its 361 pages are included fifty-one lectures, delivered by as many representative teachers, well known in their respective departments. To give even the names of subjects and authors would carry us beyond the limits of this review; while to consider the papers in such fashion as they deserve is quite out of the question. We have, however, only words of praise for the undertaking, and commendation for those engaged in carrying it out, and we venture to give expression to the hope of its continued success. This well-gathered collection of papers fairly reflects the consensus of medical opinion of the day, presenting as it does the views and practice of men actively engaged in the solution of the medical problems of their time.

The Hygiene of the Sick-room. A Book for Nurses and Others. Being a Brief Consideration of Asepsis, Antisepsis, Disinfection, Bacteriology, Immunity, Heating and Ventilation and Kindred Subjects, for the Use of Nurses and other Intelligent Women. By Wm. Buckingham Canfield, A.M., M.D., Lecturer on Clinical Medicine, and Chief of Chest Clinic, University of Maryland, etc. Philadelphia: P. Blakiston, Son & Co., 1892.

The scope of this book is indicated by the title-page. It is the outcome of a series of lectures before the Training School for Nurses of the University of Maryland.

The language of the author is clear and simple, while the information imparted is sufficiently full and accurate. The work should not only be of great assistance as a text-book in the training school, but the "intelligent women other than nurses," for whom the author writes will certainly be better able to protect their households and to assist the physician, after reading these pages. We are much pleased with the practical character of the work.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-fourth Annual Meeting, held at Milwaukee, Wis., June 6, 7, 8, and 9, 1893.

(Continued from page 56.)

Section on Ophthalmology.

Chairman: S. D. Risley, of Philadelphia.

In his address opening the meeting, the Chairman referred to the valuable work done by the section in previous years, and suggested that this could be still further improved upon by better preparation for the discussions, so that each scientific paper might bring out the experience and opinion of a large number of members of the section upon the subject which it discussed. In this way its published *Transactions* would come to occupy a merited position of authority. He suggested that each year a special subject should be chosen for discussion at the annual meeting, and a committee appointed to report upon it.

Later in the meeting, the Chairman's suggestion was adopted, and the subject chosen for consideration next year was "Methods for the Objective Measurement of Refraction," and the following committee appointed to report upon it: Dr. Edward Jackson, chairman; Dr. Swan M. Burnett, Dr. H. V. Würdemann, Dr. J. A. Thompson, and Dr. H. Gifford.

Pannus and Granular Lids.

Dr. J. A. Lydston, of Chicago, reported very satisfactory results from the use of a preparation of the digestive ferment of *caricaya papaya*, in powdered form, mixed with boric acid and dusted upon the affected surface, in severe pannus, when the cornea is the seat of thick vascular granulations. Preparations of pepsin had proved inefficient, but he had some hope that pancreatin, with which he is now experimenting, might be found of more value.

Dr. C. B. Blubaugh, of Parkersburg, W. Va., had given up strong stringent applications, such as silver nitrate and copper sulphate, in the treatment of granular lids. In cases with well-marked granulations, he scraped the surface of the lid with curets made specially for the purpose, and in addition employed milder astringents and soothing applications.

Phlyctenular Ophthalmia.

Dr. Dudley S. Reynolds, of Louisville, called attention to the frequent confusion of this disease with the ocular manifestations of hereditary syphilis. The diagnosis of syphilis is not justifiable from the ocular disease alone, but must be supported by well-recognized symptoms outside of the eye and its appendages. In the treatment of phlyctenular disease he regarded constitutional and hygienic measures as most important.

Methyl-violet in Eye-disease.

Dr. F. B. Tiffany, of Kansas City, who had originally translated Stilling's article upon pyoktanin, urged that in spite of the numerous disappointments with it, it had some value in the treatment of certain eye-diseases.

Foreign Bodies in the Eyeball.

Dr. W. H. Wilder, of Chicago, discussed the use of the electro-magnet, and reported a series of cases. He had collected altogether the reports of 258 cases, the results of which were good in 58, moderate in 40, the preservation of the eyeball without sight in 37, and failure in 123. These statistics probably show too large a proportion of cures, as a larger proportion of the successful than of the unsuccessful cases is reported. A trial of the method should be made, however, in every favorable case.

Dr. W. B. Johnson, of Paterson, N. J., reported a series of cases in which foreign bodies were retained in different portions of the eyeball, sometimes for several

years, without causing disturbance, and even with preservation of good vision. He believed that if the foreign body does not set up violent inflammation, opportunity should be given for the eye to become quiescent rather than to immediately remove it. The danger of such a course is in the risk of involvement of the second eye when the patient is not under skilled observation. On this account, the preservation of the eye should not be advised if the foreign body is probably located in the vitreous.

Sympathetic Neuritis after Evisceration.

DR. F. C. HOTZ, of Chicago, reported a case in which this had occurred, although the sympathizing eye ultimately recovered entirely. He had made measurements of the movement of artificial eyes applied after enucleation, evisceration, and over an atrophic eyeball. The extent of movement was substantially the same in each case, so that the principal argument in favor of evisceration, that it gives a better foundation for the artificial eye, is not supported by the facts; and, as evisceration causes more pain and is attended with slower healing, and on account of the danger of such complications as had been reported, it was regarded as in every way inferior to enucleation of the eyeball, when some such operation is indicated.

Meningitis following Enucleation.

DR. S. D. RISLEY, of Philadelphia, reported a case in which the eye had been removed for pan-ophthalmitis, and the patient apparently recovered, being discharged at the end of two weeks. A week later there was some suppuration of the stump, and this was followed by symptoms of meningitis and death. The patient had been from the outset in extremely bad physical condition, and there was doubt as to whether the meningitis had arisen from the inflammation of the eye, or whether both of these had a common cause.

Intra-ocular Injections of Antiseptic Solutions.

DR. G. E. DESCHWEINITZ, of Philadelphia, found that such injections always caused permanent lesions of the retina or vitreous, or both; and that they failed to cure or prevent suppurative inflammation produced in the eyes of rabbits. In one case they seemed to bring about a cure in the eye of a dog.

Dendritic Keratitis.

DR. W. H. WILDER, of Chicago, believed that cases of branching corneal ulcer, although described as instances of an independent affection, all belong to the class of herpes of the cornea, and are due to constitutional causes, malarial poisoning being prominent among them. Local treatment seemed to have little effect, except cauterization of the ulcer with carbolic acid, which produced a favorable change in one or two cases.

Brain-tumor with Optic Neuritis.

DR. E. P. MORROW, of Canton, Ohio, reported two cases with autopsies, in which violent optic neuritis, or choked disc, was the only positive sign of organic brain-disease, and furnished the first definite basis for diagnosis. In one of these a glioma, two inches long by one inch in diameter, was found at the base of the right temporal lobe, and in the other case a soft glioma was found involving a considerable part of the upper surface of cerebellum.

Optic-nerve Disease with Typhoid and Other Fevers.

DR. J. A. WHITE, of Richmond, Va., had met many cases of optic atrophy following so closely on typhoid and other fevers that it seemed clear they were the result of such diseases.

The meager literature on the subject proves only that it has not been carefully investigated. Inquiry among American ophthalmologists showed that many of them had encountered such cases, and that such affections are more common than has been supposed.

Dr. White reported one case of optic neuritis commencing at the end of the third week of an attack of typhoid fever, lasting about three months, and ending in complete recovery. A brother of this patient had suffered in a similar manner after typhoid fever some years previously.

Another case was one of atrophy, the sight having become defective during an attack of typhoid fever four months before and continuing to grow worse in spite of improved general health. Increasing doses of strychnine, up to one-fifth of a grain three times a day, produced very marked improvement in his vision.

In another case complete blindness followed remittent fever of malarial origin. Under increasing doses of potassium iodid, followed by strychnine, perfect recovery was secured within four months.

Glaucoma.

DR. L. F. LOVE, of Philadelphia, reported a series of cases of this affection, all giving the history of causation by some shock to the nervous system. He pointed out the importance of general treatment, especially the use of strychnine.

DR. H. GIFFORD, of Omaha, called attention to the value of making a small puncture in the sclerotic to diminish the tension of the eyeball before attempting iridectomy or other operation for glaucoma.

Diseases of the Lachrymal Passages.

DR. H. GRADLE, of Chicago, divided cases into two classes: those in which the obstruction and lachrymation were intermittent, occurring on exposure to wind or dust, or following eye-strain; and for which the prognosis as to rapidity and permanence of cure is comparatively favorable; and, second, those cases in which the weeping is continuous, indicating a permanent source of irritation within the nose and in the tear-passages, in which the prognosis is less favorable. He recommended the use of electroloysis in the cases of stricture of the duct in which a probe can be made to enter without undue force.

DR. C. A. WOOD, of Chicago, insisted on the necessity of recognizing the exact seat of a nasal obstruction. In the treatment, he used, for the purpose of irrigation, a reservoir situated about ten feet above the patient, connected by a flexible tube with the point introduced into the lachrymal passages. He would not practise slitting the canaliculus, unless there was good evidence that the patient would persist in the treatment until a complete

cure was accomplished. When probes are to be used, he teaches the patient to introduce them for himself, in order that they may be used more frequently and their employment be properly persisted in.

Signs of Myopia.

DR. B. A. RANDALL, of Philadelphia, discussed the curved reflex at the nasal side of the disc, described by Weiss. Though frequently present in other cases, he thought that it should be regarded as having some significance with reference to increasing myopia.

Muscular Anomalies and Squint.

DR. A. R. BAKER, of Cleveland, Ohio, reported a case of very persistent spasm of accommodation temporarily relieved by tenotomy of the external recti muscles.

DR. T. F. MURRELL, of Little Rock, found for heterophoria or latent squint, the rod-test to be the best yet proposed; but that no one test could be depended on alone. No eye subject to painful vision could be considered completely examined until tested as to the muscular balance. Imperfect muscular balance is extremely common, but frequently requires no special measures for its relief. It is most common and most difficult to relieve in neurotic patients.

DR. J. A. THOMPSON, of Kansas City, thought that operations for the correction of convergent squint, when considered in the light of ultimate results, are among the most difficult, uncertain, and unsatisfaciory in ophthalmic surgery. Glasses sometimes give relief in young children, but this is exceptional, and he is very loath to prescribe them for such patients unless there is considerable probability that they would bring about the desired result. When operations are resorted to, he thought that the operation of advancement, which should include the capsule as well as the tendon, is to be preferred to simple tenotomy.

DR. EDWARD JACKSON, of Philadelphia, presented a modification of the rod-test, combined with the rotary variable prism for the measurement of heterophoria.

DR. J. E. COLBURN, of Chicago, reported a series of cases in which squint in a portion of the visual field, permitting binocular vision only when the head was held in some peculiar position, had been relieved by appropriate tenotomies. These cases are liable to be misunderstood and subjected to treatment, sometimes operative, for wry neck, or spinal distortion. The readjustment of the eye-muscles, allowing comfortable binocular vision with the head in the normal position, is all that they required.

Orbital Growths.

DR. J. A. WHITE, of Richmond, Va., reported a case of melanotic sarcoma of the choroid, and one of fibrosarcoma, filling the orbit, both requiring enucleation of the eye. He also gave the further histories of some cases in which the removal of malignant growths had been reported a year before. In one case of melanotic sarcoma of the choroid, there had been no recurrence in the orbit, but some obscure liver-trouble, probably of metastatic development. A malignant fibroid of the orbit had remained quiet for three months, then recurred; was again removed, but incompletely; and the patient died from exhaustion.

In a case of tuberculous disease of the orbit, another growth had to be removed, and, in a case of fibroma extending back to the sphenoidal fissure, and expected to recur, no recurrence had taken place after eighteen months.

DR. R. F. LEMOND, of Denver, reported two cases of osteoma of the orbit. In one the growth was completely removed; in the other incompletely removed.

DR. H. KNAPP, of New York, said that these tumors usually spring from the cavities adjoining the orbit, and tended, if undisturbed, to involve the cranial cavity. They ought to be removed as early as possible by enucleation of the growth, working through the healthy bone-tissue surrounding it.

Cataract.

DR. H. V. WÜRDEMANN, of Milwaukee, called attention to the value of cemented bi-focal lenses after cataract extraction, giving the patient both near and distant vision without change of glasses. To avoid the apparent displacement of the floor, which patients complain of, he resorts to decentering of the lenses.

DR. B. BETTMAN, of Chicago, reported additional cases of artificial ripening of the immature cataract by his method of direct trituration of the lens without iridectomy. He has found the procedure perfectly safe and efficient.

DR. F. T. SMITH, of Chattanooga, reported a case of successful cataract extraction in a negro woman said to be 116 years old. The operation was followed by great improvement in the general mental condition.

Dislocation of the Lens.

DR. L. H. TAYLOR, of Wilkesbarre, reported a case in which both crystalline lenses were dislocated upward and outward. All of the cases of traumatic dislocation that he had seen had shown the lens displaced downward, and, therefore, he regarded this case as one of congenital displacement.

Hypertrophic Conjunctivitis.

DR. C. WILLIAMS, of St. Paul, prefers this name to trachoma, as indicating the condition present. He favors simple applications and employs a solution of mercuric chlorid of such strength as not to cause pain lasting more than five minutes. It is important to guard against implication of the iris, and, in cases in which this occurs, to use a mydriatic early and freely.

Albinism.

DR. G. M. GOULD, of Philadelphia, reported eight cases occurring in two families, neither of which gave any history of intermarriage, or of a similar defect in the eyes of ancestors. The patients showed in most respects excellent physical development. Males and females were affected, and there were intermediate children, not albinoes. He believed the transparency of the iris to be the significant condition, and the absence of pigmentation elsewhere to be of less importance. Nystagmus he regarded as the effort of healthy nerve-centers to compensate for the faulty ocular apparatus, and to locate undefined images. The partial closure of the lids, to aid in the exclusion of light, by pressure upon the eyeball caused the high astigmatism, usually with hyperopia, which these cases present. The photophobia, amblyopia, high degrees of astigmatism, and nys-

tagmus seem therefore to be due to the non-opacity of the iris. The practical means of relief are the correction of the ametropia, and the use of an opaque diaphragm with a central opening, to shield the eye from light that otherwise would be admitted through the transparent iris and lids.

Prevention of Blindness.

DR. L. HOWE, of Buffalo, urged the importance of legislation for this purpose. The census of 1890 showed the number of blind to be 50,411, an increase of three per cent. over the preceding decade. Of these, probably 5000 were blind from neglect in early childhood. Laws compelling midwives to report all cases of sore eyes in infants under their charge had been passed in a number of States, but some of them were imperfect, and the adoption of an efficient law should be urged upon the Legislatures of States which had not yet considered the subject.

The following committee was appointed to take charge of the matter: Dr. L. Howe, Chairman; Dr. G. M. Gould, Dr. J. L. Thompson, Dr. Henry Gradle, Dr. G. C. Savage.

Classification of Eye-diseases.

DR. E. JACKSON, of Philadelphia, urged that the statistics of different hospitals would have greatly increased scientific value if the same system of classification were adopted in all.

A committee was appointed to consider the subject.

Scale for Measuring the Strength of Prisms.

DR. S. L. ZIEGLER, of Philadelphia, presented such a scale, with both horizontal and vertical graduations, which he has found very convenient for ascertaining the strength of prisms, either simple or combined, or combined with lenses; or the amount of heterophoria.

Officers for the Ensuing Year.

The officers chosen for the next year are:

President—Dr. A. R. Baker, Cleveland, Ohio.

Secretary—Dr. L. H. Taylor, Wilkesbarre, Pa.

The Executive Committee consists of the former chairmen—Drs. S. D. Risley, of Philadelphia; J. L. Thompson, Indianapolis; and F. C. Hotz, Chicago.

NEWS ITEMS.

Work of the Health Department of New York.—The amount of work done in three months by the New York Health Department appears from its last quarterly report, which has just been printed. There were 167,394 inspections made and 6525 complaints attended to by the inspectors. It is evident from this that the inspectors do not wait for complaints, but that they are continually investigating dwellings and other buildings of the city. Over 2000 premises were reported for defective plumbing and over 1000 for plain filth.

Over 200 tons of fruit were condemned and seized. This includes over 60 tons of oranges and 90 tons of bananas. Over 25 tons of wine were condemned, and over 165 tons of beef, veal, sheep, and hogs.

About 500 tons altogether of food materials were taken by the department from people who intended to sell them. This mass of improper food would have been sufficient of itself to cause a great amount of sickness and many deaths. It was to be sold chiefly in the poorer quarters among the tenement-houses and in the Polish-Jewish neighborhood around Hester and Essex Streets. On account of the low price at which it was held it would have found ready purchasers.

There were removed from the streets over 2500 dead horses, and over 2000 dead calves, besides dead sheep, cows, and several thousand dead cats and dogs.

During the quarter there were reported 5485 cases of contagious diseases, almost all of them scarlet fever, measles, or diphtheria. Over 16,000 pieces of infected goods were received. About a third of them was destroyed; the others were disinfected.

Since the city hospitals for the care of patients sick with contagious diseases have been completed the number of cases of contagious diseases has decreased. The proportion of deaths to the number of cases has also decreased. The hospital mortality from scarlatina was less than 11 per cent., and from diphtheria less than 18 per cent. The higher death-rate from diphtheria was caused by the deaths of children under five years of age. Only the worst and most dangerous cases of contagious disease are taken to the hospitals for isolation and treatment, so the death-rate is higher there than throughout the city, but even with this selection the mortality from typhus fever only reached 34½, measles 21, and scarlet fever 5 per cent. There is one case of leprosy at the Riverside Hospital on North Brother Island. It is noticeable that three-fifths of the cases of typhus fever are in foreign-born persons, and that the death-rate is higher among such cases than among the American-born patients. About one-fourth of the cases of typhus fever came from one house, 34 Bayard Street. The lodgers were disinfected, as was also everything about the place. A complete list is printed of the typhus patients with their names, ages, dress, occupation, and nativity.

The number of deaths in the city during the quarter was 11,844, and the death-rate 25.37—lower than for three of the preceding four years.

The cause of the greatest number of deaths was pneumonia, 2389; next to that pulmonary tuberculosis, 1381. None of the other causes of death exceeds a thousand. There were 95 deaths from alcoholism, 160 from old age, 348 from accident, 8 from homicide, and 64 from suicide.

Dr. John C. Hall, a well-known alienist, died on July 4th, in an attack of angina pectoris. He was graduated from the University of Pennsylvania in 1868, and became a resident physician in the Philadelphia Hospital. In 1878 he was made Superintendent of the Friends' Asylum at Frankford, a position that he held up to the time of his death.

Oscar Israel, for many years an assistant of Virchow's, has been made an extraordinary professor of pathologic anatomy in the University of Berlin.

Prof. Renvers has been designated as the successor of Guttmann, recently deceased, as the director of the medical department of the Hospital Moabit at Berlin.

v. Eiselsberg, one of the assistants at the clinic of Billroth, in Vienna, is in contemplation as the successor at Utrecht of Salzer, recently deceased.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIII. SATURDAY, JULY 22, 1893. NO. 4.

ORIGINAL ARTICLE.

SYRINGOMYELIA.

BY LEO NEWMARK, M.D.,

PHYSICIAN TO THE SAN FRANCISCO POLYCLINIC, SAN FRANCISCO, CAL.

IN a recent work[1] on diseases of the nervous system it is stated that "it is now quite a fashion in this country to report so-called cases of syringomyelitis." It it be a fashion it is one that seems to have but few votaries in the United States. For, since the publication of the first case by Dr. Starr,[2] certainly not many more than a dozen American cases have been recorded. The paucity of our literature on syringomyelia forms a striking contrast to the voluminous records of European authors on the subject. Schultze, Déjerine, Charcot, Hoffmann of Heidelberg, and many others have been enabled to base their studies of this disease on such abundant material as to justify the assertion that it is scarcely less common than disseminated sclerosis. Hoffmann alone recorded five cases in 1891,[3] and recently, in a very elaborate essay,[4] added a report of no fewer than eighteen.

Assiduously as syringomyelia has been studied for several years past, the interest in it does not seem to flag. Its pathology and the relations of the structural changes in the cord to the clinical manifestations are still subjects of laborious research. The diagnostic difficulties arising from its resemblance to certain other diseases render its study especially important. The question of its identity with Morvan's disease has not yet been answered to the satisfaction of all; and its resemblance to anesthetic leprosy has called forth the sensational assertion that syringomyelia and anesthetic leprosy form "a single morbid entity," varied only by climate or the hygienic conditions of the patient.[5]

In view of the sustained interest in all that concerns this remarkable malady, the report of the following case may not be unacceptable.

[1] "A Treatise on Nervous and Mental Diseases," by Landon Carter Gray, M.D., 1893.

[2] American Journal of the Medical Sciences, May, 1888.

[3] Volkmann's Sammlung, 1891, No. 20.

[4] Deutsche Zeitschrift für Nervenheilkunde, Bd. iii.

[5] Zambaco: Gaz. hebd., 1891. Quoted by Marestang, Revue de Méd., 1891, p. 783. In La Semaine Médicale, 1893, June 10, Zambaco maintains that not only Morvan's disease and syringomyelia, but also sclerodermia, sclerodactylia, aïnhum, morphea, and local asphyxia with symmetrical gangrene, are "nothing but varieties of one and the same prehistoric disease, old as the world, leprosy."

The patient, K. F., is an unmarried woman, twenty-five years old, a native of Boston, Mass., of Irish parentage, and resident in California since her second year. She presented herself at the San Francisco Polyclinic on the 13th of January last, with the statement that her hands were wasting, and added that she was insensible to pain or heat in the upper extremities. The disease began about six or seven years ago with a prickling sensation ("like when the foot is asleep") in the right deltoid region; this sensation gradually descended to the elbow, and thence down the forearm to the wrist; it has never been present on the left side. The patient found relief from the distressing feeling by directing her companions to strike her on the fleshy part of the right arm, and the more vigorous their blows the greater was the relief. She did not cease to be troubled in this way until about a year and a half later; in the meantime she had continued her occupation as a seamstress. While engaged in sewing and ironing she often sustained injuries to her hands which, although severe, entailed no suffering, and thus attracted her attention to the impairment of her sensation. She often burned herself and did not notice it until it had been pointed out to her; once she put her hand into very hot water and scalded it, but suffered no pain. Her fingers finally became very sore, so sore that she thought "they must rot off," and some of the nails fell off two or three times. About four years ago she abandoned her occupation and has since then injured herself less. While undergoing electric treatment the regulation of the strength of the constant current was occasionally left to the patient by her physician, and there being no painful sensation to warn her, a large running sore formed in the palm of the left hand, which healed very slowly, but did not distress her. The disturbance of sensation preceded the wasting of the hands. The right hand wasted first; there was twitching in the fingers and especially in the thumb, in which there was a sensation "like the fluttering of a bird trying to escape." The right hand had wasted to its present condition when (about three years ago) the atrophy of the left commenced. The patient is often annoyed by a jerking of the left lower limb; the jerking consists in violent flexion of the thigh and extension at the knee; it occurs most frequently and is most violent when the patient is recumbent and, according to the testimony of the mother, during sleep. It sometimes occurs while she is sitting, and is then arrrested by standing. Fatigue after much walking intensifies the jerking. Occasionally there are cramps in the great toe of each foot, in which the toe is forcibly extended. Complaint is further made of pain at the back of the neck and in the palm of the hand.

Nothing was elicited indicating a family tendency to nervous diseases; but there seems to be a tuberculous taint, as the patient's father and sister and a maternal uncle are said to have died of pulmonary tuberculosis.

The patient is at present small and anemic. In both hands there is advanced muscular atrophy. The interossei are wasted, the absence of the interosseus primus being particularly noticeable. The thenar and the hypothenar eminences are flattened, the right thenar less than the left. The distal and middle phalanges are flexed, and the proximal phalanx is extended, whereby the "claw-hand" is produced, more markedly, however, on the right than on the left side. Flexion and extension at the wrist are preserved; but the atrophy of the intrinsic muscles of the hands is so great as to render the left hand practically useless and to seriously impair the use of the right. The advantage of the right hand over the left is due to the better condition of the opponens and the adductor pollicis in the former, and of the muscles in the right forearm. Abduction, extension and flexion of the thumbs are fair. Both forearms are thin, but the left is thinner than the right, the latter measuring 13 cm., the former only 12 cm. in the middle. The muscles of the upper arms and shoulder appear a little flabby, but not more so than might be expected from the patient's general nutrition; their functions are intact. The right arm measures 19.5 cm., the left 19 cm. around the middle. There is no atrophy of the trunk or of the lower limbs.

Fibrillary twitching is seen in the muscles on the inner side of the left forearm and in those of the hands; there is also a jerky tremor of the hands. As to the electric reactions, the muscles supplied by the musculo-spiral nerve react on both sides equally well and normally to direct and indirect galvanic and faradic excitation. The right median and ulnar nerves and the muscles of the forearm to which they are distributed respond fairly well but less promptly than the extensor muscles; in the same nerves and muscles of the left limb there is a considerable diminution of excitability by either current, without modal change, and the reduction of irritability is greater in the ulnar than in the median nerve and muscles. There is no typical reaction of degeneration in the small muscles of the hands; in accordance with what has been noted of the comparative preservation of motor power in the right thumb, contractions of the adductor and the opponens pollicis are obtainable by direct excitation or by excitation of their nerves at the wrist, with not very strong currents; in the other muscles of both hands the electric reactions are either greatly diminished or abolished.

The tactile, muscular, and stereognostic senses are preserved in all parts.

While the muscles of the upper extremities were being tested by faradism the patient gave no indication of pain even when strong currents were applied with a very small electrode. Other tests, however, disclosed that the analgesia was not absolute in these parts, deep punctures and strong pinches, particularly in the right hand and shoulder eliciting evidence of painful sensation. The analgesia is more profound throughout the left superior extremity than upon the right. It is most profound on the left side of the head (except a part of the face), on the left half of the neck and the left shoulder. It is slight, but still evident in comparison with the other side, on the median half of the left side of the face and on the left side of the mouth and tongue. The upper and lower regions of the chest are slightly analgesic, while the breasts are normal or nearly so. Ammonia held to the nostrils produces equal irritation on both sides. The analgesia in the hands is not as great as the statements of the patient would lead one to believe. The ulnar nerves are not sensitive to strong pressure at the elbows.

The insensibility to heat and cold coincides for the most part in distribution and degree with the analgesia. In the right hand it is less than in the left, and is far from absolute, although the impairment of the thermic sense is beyond doubt; but it is less than would be inferred from the history of the patient's experience. A piece of ice can be retained in the left hand almost indefinitely without causing discomfort, whereas in the right a stinging sensation of cold is announced after it has been held a short time. Water which was quite hot when applied to the right hand for the purpose of electric testing was not felt to be at all warm, whereas subsequently a test-tube filled with moderately warm water was distinguished from one filled with water of about 60° F.; and the distinction was made between the wooden handle and the metal part of a percussion hammer, when held in the right hand, by the temperature of the metal. The patient herself, however, when informed of the result of the tests, remains convinced of the insensibility of her hands to painful impressions, heat and cold, under ordinary circumstances. A piece of ice taken into the left side of the mouth is recognized as cold, but is immediately felt "several degrees colder" when shifted to the right side. An analogous difference obtains in regard to warm water. Dissociation of the temperature-sense itself was not observed.

Trophic changes are not pronounced apart from the muscular atrophy. A few insignificant scars indicate the sites of former injuries. The nails are not abnormal.

Nor are the vasomotor disturbances marked. On the chest and back the vasomotor irritability seems to be increased; this is especially noticeable when the finger is passed along the row of spinous processes. The hands are, as a rule, subjectively and objectively quite cold.

The iris-reflex is normal in either eye. The left conjunctival reflex is absent; the right one is present. The pharyngeal reflex is preserved. A brisk jaw-jerk can be obtained. The triceps-tendon reaction can be elicited in either arm. On percussion the supinator longus on each side contracts actively. No periosteal or tendon-reflexes exist at the wrists. The epigastric reflexes are absent. The knee-jerks are both much exaggerated, and are equal on the two sides. The tendo Achillis reflexes are quite active. The front-tap contraction is obtainable on either leg. Ankle-clonus was elicited on the left side at

one examination, but has not been produced since. The plantar reflexes are absent.

Hearing, taste, and smell are normal. The eyes were kindly examined for me by Dr. Pischl. V. with + 1.5 = 6/VI in both eyes. The field of vision determined for white and colors is normal. The ophthalmoscope reveals in the right eye a band of opaque nerve-fibers encircling the inner half of the papilla and equal in width to three-fourths the diameter of the disc. In the left eye a small patch of such fibers is seen at the upper, and another at the outer, edge of the disc. The papilla appears a little redder than is normal, which is probably due to the contrast with its white environment. There is a slight narrowing of the left palpebral fissure, its width being 8.5 mm., while that of the right is 9.0 mm.

The secretion of tears is more abundant in the left eye than in the right. As has already been mentioned, the left conjunctival reflex is abolished. The pupils react to light and in accommodation, and are equal. There is no nystagmus.

The spinal column is not tender to pressure. There is no scoliosis. On passing the finger down the row of spinous processes a peculiarity is felt in the shape of some of them in the lower dorsal and upper lumbar regions. The ninth dorsal spinous process is normal; the tenth is clubbed; the eleventh and twelfth dorsal and the first lumbar are clubbed and bifid; the second lumbar is like the tenth dorsal and the rest are normal.

The treatment since the patient has been under my care has consisted chiefly in the exhibition of iron. Her general health has improved, and she is now free from the pain in the back of the neck, but still complains occasionally that the hands ache.

The combination of symptoms such as have been described in the foregoing notes, consisting in progressive muscular atrophy of the Duchenne-Aran type and dissociation of sensory impressions, stamps this as a classical case of syringomyelia. If it be at all necessary to differentiate this malady from Mor van's disease, the absence of painless whitlows will be conclusive of the diagnosis.

How close the clinical resemblance between syringomyelia and anesthetic leprosy may be, despite the difference in pathology, is evident from the descriptions and illustrations furnished by Marestang. Dissociation of sensation has been observed by this author in leprosy; but only in one case among over one hundred was there retention of tactile sense with analgesia and thermoanesthesia, while in two cases there was retention of pain and of the thermic sense with tactile anesthesia. On the other hand, in syringomyelia loss of sense of contact has not infrequently been met with (which is not surprising, in view of its pathology). Such dissociations, however, are exceptional in leprosy, and the preservation of tactile sensation in syringomyelia is the rule. The muscular wasting in the extremities is similar in the two diseases, and even the atrophy of facial muscles, often seen in leprosy, has been observed in four cases of syringomyelia. Nevertheless a proper appreciation of what is frequent and what is rare in each, or the recognition of some characteristic of leprosy, such as anomalies of pigmentation, loss of hair, nodular thickening of nerves, the bacillus, etc., will generally lead to a diagnosis. But that errors may occur has been recently shown by Pitres[1] in his report of the case of a man who, presenting trophic disturbances and the sensory dissociation of syringomyelia, was for a long time considered to be suffering from that disease until the detection of Hansen's bacillus in a cutaneous nerve proved him to be affected with leprosy. This man had lived for three years in Martinique, and it is in countries which are in frequent communication with endemic foci that special caution is required. The Pacific coast is exposed to the occasional intrusion of lepers from Hawaii or China, and in the public eleemosynary institutions of San Francisco there are now thirteen lepers. But in the present instance, besides the absence of anything in the patient's antecedents likely to excite a suspicion of leprosy, and the lack of any symptom characteristic of that disease, the insensitiveness of the nerves to pressure, the fact that the disturbance of sensation is less profound at the peripheral parts of the upper extremities than in certain other regions, the fibrillary twitching, the augmented knee-jerks and the narrowing of the left palpebral fissure, decide in favor of syringomyelia.

Hysteria, that arch-mimic of organic nervous disorders, has also been known to simulate syringomyelia. Cases of this kind have been reported by Charcot[2] and by Rossolimo.[3] The latter tells of a girl, aged twenty, with interosseal paresis, analgesia, and thermoanesthesia, but only slight diminution of tactile sensation, in her hands. This combination of symptoms had recurred six times, in the course of a year and a half, at regular intervals, and disappeared promptly after an hypnotic séance. To discuss the possibility of the hysterical nature of the case now under consideration would appear like raising objections to a diagnosis simply for the pleasure of refuting them. Nor does it seem necessary to enumerate the features distinguishing cervical hypertrophic pachymeningitis from syringomyelia, the anesthesia in the district of cranial nerves alone sufficing to exclude the former.

The possibility of diagnosticating syringomyelia during life is not yet universally conceded. In the discussion of a case presented before the Neurological Society of New York, in 1890, the president, Dr.

[1] Gaz. des Hôpitaux, 1892, No. 137; abstract in Neurolog. Centralblatt, 1893, p. 102. See also Kalindero: Wiener med. Presse, 1892, No. 39.

[2] Leçons du Mardi, 1888–1889, p. 518.

[3] Neurolog. Centralblatt, 1892, p. 493.

L. C. Gray, said: "The only way to make a diagnosis of syringomyelia was to make an autopsy."[1] And the same view is expressed in his recent *Treatise on Nervous and Mental Diseases*,[2] although he acknowledges "that we are on the right track and that we shall be able to make a diagnosis in the early future." The fact is, however, that the diagnosis has been repeatedly made *intra vitam* and verified *post mortem*. Charcot[3] stated in 1889 that Schultze had twice and Kahler once found the diagnosis justified at the autopsy. Moreover, Déjerine,[4] in 1890, and again in 1891,[5] and with Sottas,[6] in 1892, reported cases in which the diagnosis of syringomyelia, which, during life, had been based on the muscular atrophy and the sensory dissociation, was corroborated after death. Verified diagnoses have also been recorded by Gyurman,[7] Critzmann,[8] and Bernstein.[9] In a report of a case of syringomyelia by Hughlings Jackson and Galloway[10] mention is made of an instance in which a diagnosis of Ferrier's was proved to be right at the necropsy. In Hoffmann's[11] Cases IX and XIV the disease had been recognized during the lifetime of the patients. Finally, the reviewer of Dr. Gray's book in the *American Journal of the Medical Sciences* for March, 1893, states that two cases of syringomyelia have been diagnosticated *intra vitam* in Philadelphia, and that the autopsy confirmed the diagnosis; the cases had, however, not yet been published. One of them is, perhaps, identical with that very recently recorded by J. H. Lloyd.[12]

This list makes no pretensions to being exhaustive, but it will suffice to show that the diagnosis may be ventured with some degree of certainty. Not all of the cases conformed to the most frequent type, but the pathognostic value of progressive amyotrophy with impairment, and generally dissociation of sensation, was sufficient to guide the observers to the recognition of the disease. The assumption of syringomyelia explains the course and the symptoms of the case with which we are dealing. The process of gliosis, taking its origin in the gray substance behind the central canal in the lower cervical region and extending into the posterior cornua, produced the subjective and objective disturbances of sensation in the upper extremities; ascending in the left posterior horn into the central regions of the occipital nerve and of the sensory part of the trigeminus, it impaired sensation in the left side of the head and face, and, descending into the dorsal part of the cord, rendered sensation on the trunk abnormal; the invasion of the right and left anterior cornua, successively, in the lowest cervical and first dorsal segments, gave rise to atrophy of the small hand-muscles in the same order, and, from the wasting of the muscles of the left fore-arm, it is evident that the destructive process is extending into the anterior horn higher up. The distressing jerking in the left lower limb may possibly be due to irritation of the lateral pyramidal tract on the same side. It may be mentioned that a similar symptom was noted in one of Schultze's[1] cases.

The loss of the left conjunctival reflex is due to the sensory disturbance in the distribution of the fifth nerve, and the slight narrowing of the left palpebral fissure is ascribable to the implication of sympathetic fibers in the lesion at the lowest cervical and uppermost dorsal segments. There is no concentric limitation of the field of vision. According to Hoffmann,[2] limitation of the visual field has been observed by Déjerine and Tuilant in seven, and by Morvan in five cases of syringomyelia, without hysteria; by other authors it has been found in five patients with syringomyelia in whom hysteria was either certain or at least probable; and it was absent in 26 cases. Including the present instance, therefore, its absence has been noted in 27 out of 44 cases of syringomyelia. Its comparative frequency in the French cases is conspicuous.

The opaque nerve-fibers in the retina merit some attention. This anomaly is rare. Manz,[3] of Freiburg, states that he found this opacity mentioned only 154 times in the records of half-a-million patients with ocular diseases. But among 113 psychopathic male inmates of a Freiburg institution opaque nerve-fibers were observed in the eyes of four. Manz had already previously[4] called attention to the possible value of this, as well as other congenital anomalies of the eye, as indicating a neuropathic predisposition, although they are not necessarily pathologic; and he suggested that they were likely to be found associated with certain diseases dependent on congenital abnormalities of the central nervous organs. Now, according to the prevailing theory, the origin of syringomyelia is to be sought in a defect in the developmental tendency of the spinal cord, or, as Hoffmann more definitely expresses it, in a defective closure of the embryonic canal, whereby germinal cells are retained in the line of closure which

subsequently proliferate and lead to primary gliosis. In support of the view that a defect in the original constitution of the central nervous system is responsible for the development of syringomyelia Hoffmann adduces some cases in which that disease was combined with other nervous diseases generally considered as arising from a congenital predisposition, and in others in which at the autopsy abnormal anatomic features were found that must be regarded as developmental errors. Among the latter are mentioned an abnormal strand of white fibers in front of the anterior commissure, heterotopia of gelatinous substance in a posterior column, heterotopia of gray matter, etc. The presence of medullated (opaque) nerve-fibers in the retina is submitted as an addition to this list.

In conclusion, the peculiar form noted in some of the spinous processes may be alluded to as perhaps indicating some developmental irregularity.

THE VALUE OF STRYCHNINE IN THE TREATMENT OF DISEASES OF THE LUNGS.[1]

BY THOMAS J. MAYS, M.D.,
PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC, AND VISITING PHYSICIAN TO THE RUSH HOSPITAL FOR CONSUMPTIVES IN PHILADELPHIA,
PHILADELPHIA, PA.

ABOUT five years ago I began the use of strychnine in the treatment of asthma, with good effects, and believing, as I did then and as I still do, that probably most pulmonary diseases have a pathologic basis similar to that of asthma, or in other words that they are intimately related to the nervous system, I have since been induced to test the efficacy of this drug in the treatment of the various inflammatory affections of the respiratory organs; and my purpose this evening is to give an account of the results of its administration, and also to present my views as to its therapeutic action in these diseases.

It is well known that no drug in the materia medica affects the nervous system more profoundly than strychnine. Its action is principally confined to the medulla oblongata, the spinal cord, and the peripheral motor nerves. Consciousness and the higher nerve-centers seem to be wholly unaffected by it. It is a most powerful stimulant in small doses; a convulsant in medium doses; and a narcotic or paralyzant in large doses. The narcotic or paralyzant action of strychnine is generally overlooked in the discussion of its physiologic properties; but it has been very well demonstrated, especially by Reichert, that, if large doses are injected, no convulsions occur, the animal becoming as limp as if it had been paralyzed by a large dose of morphine or of curare.

Strychnine also differs greatly in action from other stimulants, inasmuch as its stimulating stage occurs markedly and pronouncedly before its convulsant or paralyzing phases. Besides its general action on the medulla oblongata, spinal cord, and peripheral nervous system, strychnine possesses a special influence on the respiratory centers and pneumogastric nerves. In man and in animals it accelerates the breathing movements and provokes deeper and fuller inspirations. Indeed, when excessive doses are given, so that convulsions are excited, this influence is so great that the thoracic movements are arrested at the period of maximum inspiration. While this is true of the action of large doses of strychnine on normal respiration, the drug has an opposite effect if given in smaller or stimulant doses when the breathing is hurried from disease. This I have confirmed by clinical observation in cases in which the abnormally high respiration-rate was incidental to nervous exhaustion accompanied by subnormal temperature. The same is true of its action on the heart. In large doses it accelerates the movements of this organ, but in smaller doses, given hypodermatically, say from $\frac{1}{30}$ to $\frac{1}{20}$ of a grain, I have seen it reduce the cardiac pulsations from 100 to 84 in the course of a few minutes.

Over and above its stimulating action on the nervous system, or perhaps indirectly through the sympathetic and pneumogastric nerves, strychnine possesses the power of increasing the absorption of the products of digestion in the alimentary canal and of enhancing the blood-building process. This observation we owe to the brilliant researches recently made by Professor Hofmeister and his pupil Dr. Pohl.[1] Before these experiments were made we knew little or nothing concerning the function of alimentary absorption, except that the food-products were taken up in some fashion by the bloodvessels and by the lacteals of the stomach and of the intestines. That the albuminous food is changed into peptone had been demonstrated clearly enough; that peptone does not enter the blood in a free state was also plainly evident from the fact that it is not found as such in the blood, and that when injected into the blood it acts as an active irritant and poison, and is rapidly eliminated by the kidneys.

Now, Professor Hofmeister has demonstrated in these experiments that during digestion there is a very decided augmentation in the number of white blood-corpuscles formed and developed in the adenoid tissue or lymphatic glands of the alimentary mucous membrane; that these corpuscles imbibe and incorporate the peptone formed by the digestive process; and that the peptone loses its identity in and is distributed by them to the tissues of the body by way of the circulation. It does not concern us here to know whether the tissues of the body take up the nutritive material from the white blood-corpuscles or peptone, or whether peptone is changed into some other form of albumin before it reaches its destination.

That which is of the greatest interest here, however, is the investigation of Dr. Pohl, who studied the physiologic influence of different kinds of food and drugs on the white blood-corpuscle formation in the lympathic tissue of the alimentary canal. He counted the number of white blood-cells in the blood of dogs before and after these foods and drugs were administered by the mouth, and found an average increase in these cells of more than 100 per cent. after the ingestion of albuminous foods, but no increase in their number when carbohydrates, fats, alcohol, salts, water, and foods of a non-

[1] Delivered to the Polyclinic Class, February 6, 1893.

[1] Archiv für experimentelle Pathologie u. Pharmakologie, vol. xix, p. 1, and vol. xxv, p. 31.

albuminous nature were given. On the other hand, he tested the action of strychnine and of other medicinal agents in the same manner, and discovered that some were inert, while others had a most remarkable influence in this respect. For example, he found that strychnine, which was one of the best agents, nearly equalled beef in its power of augmenting the number of colorless blood-cells.

In estimating the therapeutic value of strychnine we must, therefore, not overlook the property which it possesses of enhancing the process of white blood-cell formation. This means a great deal. It means that, in addition to its other functions, it is a genuine blood-builder. It means that it greatly aids the lymph-glands of Peyer, with which the intestinal walls are studded, in common with the spleen and the other lympathic glands throughout the body, in transforming and organizing reserve nutritive material into white blood-cells. The importance of this influence will be fully realized when we consider that recent advances in physiology make it exceedingly probable that a large number of red blood-corpuscles are nothing but transmuted white blood-cells—the change consisting chiefly in a transformation of the protoplasm of the latter into hemoglobin and stroma. Unlike food, strychnine does not supply the material from which these cells are formed, but it furnishes the force which stimulates to increased activity the organs whose function it is to generate them. To sum up, then, the action of strychnine, it can be said that over and above its influence on the general spinal nervous system, it acts specifically on the medulla oblongata, on the respiratory centers, and on the pneumograstric nerves, and additionally possesses the power of invigorating the blood-making process.

In the present state of therapeutics it goes without saying that if there is not, there should be some rational indication in any given disease for the remedial agent that is employed. What then, viewed from this standpoint, is the indication for the administration of strychnine in the various forms of pulmonary disease? I have already intimated my belief that diseases of the lungs are closely associated with disease of the nervous system, and I will go further and say that this relationship is one of cause and effect—that the diseases of the lungs exist in virtue of disease of the pneumogastric nerves and other parts of the nervous system.

It is exceedingly strange that, in spite of the great advance recently made in the study of diseases of the nervous system, the physiologic and pathologic connection between the lungs and their nerve-supply has been practically ignored. The lungs are innervated by the largest and most important nerves in the body, yet nearly all the diseases that affect these organs are at the present day attributed to the influence of irritants introduced from without, and the possibility that the fault may reside in the nerve-supply does not even receive serious consideration. This is indeed exceptional, for it is not in the least true in disease of other organs. When, for example, an arm, or a leg, or an eye becomes subject to certain forms of disease, immediate inquiry is made into the state of their nerve-supply, which is often found to be wholly responsible for the disordered manifestation. Paralytic ophthalmia, which has been described by Serres, Herbert, Mayo, Abercrombie, Stanley, and others, is, owing to the experiments of Magendie, known to depend on disease of the trigeminal nerve. Ulceration of the skin and subjacent tissues follows injury to the spine. Cutaneous inflammations, like zoster, eczema, acne, pemphigus, erythema, excoriations, elephantiasis, etc., are often sequential to diseases of the nerves that supply the affected parts. Intermittent ophthalmia, intermittent otitis, intermittent arthritis exist in virtue of intermtttent neuralgia of the supplying nerves. Peripheral neuritis gives rise to herpes intercostalis, frontalis, preputialis, etc., and it is also demonstrated that leprosy, scleroderma, and the disease first described by Paget, under the name of *glossy skin and fingers*, are intimately associated with the underlying nerves.

Now when all these general facts are connected with the special one that experiments almost without number have been made on animals, which, with hardly an exception, show that many of the catarrhal and inflammatory affections of the lungs follow division of or injury to the pneumogastric nerves, there is cause for still greater surprise at the persistence with which this frequent source of lung-disease has been disregarded. I am well aware that this pulmonary degeneration is known by the name of "Schluck" or deglutition pneumonia, which implies that it is not primarily due to vagus-injury, but to the entrance of mucus, saliva, particles of food, etc., into the lungs, owing to the insensibility of the larynx and paralysis of the esophagus, sequential to operation. Aside from the fact that this is a weak and irrelevant argument, in so far as the final cause of this phenomenon is concerned, Arnsperger[1] and others have shown that if, after section of the nerves in question, a tube is inserted in the trachea, and the admission of foreign bodies into the lungs is prevented, the same pulmonary changes occur. But even if it were clearly demonstrated that, owing to a defect of nerve-influence in the larynx and pharynx, particles of food, mucus, saliva, and other secretions of the mouth and pharynx penetrate the lungs, and have the power of setting up pneumonia in animals, which no one has yet shown, we would, after all, have to inquire whether or not the same conditions and the same train of phenomena may develop in man as a sequel to disease of the vagus and its branches.

It is not necessary, however, to look to experiments on animals alone for proof that lesions of the pneumogastric nerves are capable of producing various pulmonary diseases, for there are many instances on record in which pulmonary consumption, pneumonia, bronchitis, etc., have occurred as a result of disease of these nerves, as will be seen from the tabular report[2] of about one hundred and fifty cases which I gathered from the literature on this subject, and which show the intimate dependence of the one on the other. Aside from this evidence I shall take the liberty of quoting the opinions of medical men whose attention had been especially directed to this subject, and who are abundantly capable of passing intelligent judgment on it.

As early as 1850 Dr. J. C. Holland regarded pulmonary consumption as "a disordered condition of the nervous system." In 1871 Dr. Clifford Allbutt[3] describes a

[1] Virchow's Archiv, vol. ix, pp. 197 and 437.

[2] Pulmonary Consumption a Nervous Disease. 1891. George S. Davis, publisher, Detroit, Mich.

[3] Medical Times and Gazette, 1871, vol. ii, p. 613.

variety of phthisis which he calls the neurotic type, and he says of it: "The more I study the relations of the disease the more satisfied I am that the lung-mischief is also a neurosis—by which I mean that the lesion is one not originating in the local tissues, but in the nervous system." Laycock[1] says that "Defective pneumogastric innervation upon a loss of cerebro-spinal power is a very common predisposing and exciting cause of phthisis." In discussing a paper on "Pneumo-paresis," read by Dr. W. B. Richardson before the London Medical Society, Dr. J. Hughlings Jackson remarked that he regarded acute pneumonia as a form of herpes zoster of the pneumogastric nerves.[2] Dr. Peter[3] states that neuralgia of the pneumogastric nerve is very common in pulmonary phthisis, as may be shown by making pressure over the nerve in front of the scaleni. Dr. Fernet[4] holds that so-called fibrinous pneumonia is a herpes of the lungs, brought about through neuritis of the pneumogastric nerves. Drs. Bianchi and Armandi[5] report that in eleven cases of terminal pneumonia in paralytics they found neuritis of the vagi in every instance.

Dr. Bianchi[6] discusses a form of pneumonia that frequently occurs in paralytics, but which differs clinically and anatomically from croupous pneumonia. The temperature is usually below 39°, while the pulse varies from 50 to 140 beats; cough and expectoration are absent sometimes, and the respiratory movements are feeble, slow, and superficial. Percussion and auscultation do not always give positive results. Fibrinous exudation is seldom present, and the affected lung usually remains in a hepatized condition. Frequently there exist larger or smaller gangrenous foci, and nearly always, if the case is of long standing, a puriform infiltration of the bronchi and alveoli. All of these manifestations simulate those of pneumonia following section or compression of the vagi, and which the author generated in rabbits and dogs. In a number of paralytics who died of pneumonia he was able to trace a primary degenerative atrophy of the vagi, and hence he believes that these pneumonias are dependent on vagus-degeneration. He does not accept the doctrine of Traube and Frey that this disease is engendered by the swallowing of food, etc. (*Schluck-pneumonie*).

Prof. Baelz[7] states that in the Japanese University he teaches that pneumonia is a reflex vasomotor exudative neurosis. Goodhart[8] says: "I really believe that injuries to the head are quite capable, by interfering with the control-power of the nervous centers, of leading to disordered function in the first instance, and in the second to such pronounced organic departures even as an acute pneumonia." Dr. Jappa,[9] who examined the peripheral nerves in the bodies of fifteen persons dead of pulmonary phthisis, found marked degeneration in every case. He states that in these patients there were no nervous symptoms during life other than those found in almost all cases of the kind, such as undefined muscle-pains, neuralgia, hyperesthesia, etc. Dr. Lewin,[1] in a minute study of the ganglion of the trunk of the vagus in twenty cases of pulmonary phthisis, found it degenerated in every instance. Busi[2] states that in many cases we must regard tuberculosis and insanity as an expression of the same constitutional weakness. In 50 per cent. of the cases of insanity which he collected in the Asylum for the Insane at Basle there was tuberculous heredity; in 47.2 per cent. there was neuropathic heredity; and in 20 per cent. there was a mixture of neuropathic and tuberculous heredity. Dr. O. Vierordt[3] states that on the whole no decided opinion can yet be given on the subject of the relationship between pulmonary phthisis and peripheral nerve-degeneration, but the indications of such a possibility are so apparent that a further investigation is demanded. Clouston[4] states that "The evidence seems to show that if tuberculosis cannot itself be called a neurosis, it is in most cases dependent for its existence on a trophic neurosis, or has the closest affinity to it."

Dr. Samuel Wilks, in commenting on a case of neuroma, says:[5] "It has been said that the patient died of phthisis, and these tumors were found accidentally; but in all probability the affection of the nerves, that is, of the pneumogastrics, was the cause of the pulmonary disease, and, therefore, so far from neuroma being a harmless affection, it was the cause of the girl's death. This idea is suggested by the observation of several cases of pneumonia occurring in connection with disease of these nerves—particularly as witnessed in aneurism of the aorta and cancer of the esophagus. In these diseases death is often brought about by the pulmonary complication, and the pneumogastric nerves are found implicated in the disease or pressed on by the tumor."

On a case of fibroma in the posterior mediastinum, the eminent Sir Wm. Gull[6] made the following remarks forty years ago: "This case affords an excellent illustration of the effects which are referable to paralysis of the pulmonary plexus on one side—accumulation of muco-purulent secretion in the paralyzed bronchi, subsequent dilatation of the tubes at their peripheral distribution, concomitant exudation into the air-cells, hepatization, and, at length, disintegration of tissue. . . . . It is one of the evils of a too exclusively humoral pathology [bacillary pathology, we might substitute at the present day—Mays] that it leads us to overlook the minute anatomical relations of disease, which are in themselves often a key to the sequence of morbid changes. These cases illustrate this proposition, for the possible local effects on the lung of injury to the pneumogastric and pulmonary plexus being recognized, whenever cause for that injury exists we may anticipate its results, and are not wholly dependent on physical examination, as we are if we limit our pathological view to the mere changes in the lung, without considering how they are produced."

[6] Guy's Hospital Reports, 3d series, vol. v, p. 307.

From what has so far been said it is obvious that we possess both experimental and clinical evidence, of the most incontrovertible character, that many forms of pulmonary disease may and do originate through the intervention of disease of the pneumogastric nerves. By this it is, of course, not implied that one must look for a compression of these nerves by aneurisms, tumors, or enlarged glands in all cases, but that we must recognize the fact that any depression or poisoning of the nervous system, whether this is produced by peripheral neuritis, by disease of or injury to the spinal cord or the brain, by cerebro-spinal meningitis, influenza, diphtheria, beri-beri, leprosy, whooping-cough, alcohol, syphilis, diabetes, mercury, lead, brass, etc., is always capable of producing pulmonary degeneration. It is just as reasonable to believe that many pulmonary affections are developed through pneumogastric disease as it is to believe that asthma, which is universally regarded as a neurosis, and which leads to bronchitis, pneumonia, and phthisis, is developed through the same channel. I have on a number of occasions shown the great utility of strychnine in the treatment of asthma before this class, and if clinical experience is able to demonstrate, as I feel confident it will be, that the power of strychnine to alleviate bronchitis, pneumonia, phthisis, etc., is of no less importance than it is in asthma, it is another strong link in the chain which supports the theory that most pulmonary disorders are primarily and throughout largely nervous in nature. Indeed, if strychnine has any value whatever in these diseases, no other possible conception of its action can be formed than that which it possesses through its influence on the nervous system.

The General Therapeutic Action of Strychnine in Diseases of the Respiratory Organs.

There are very few drugs in the materia medica the beneficial effects of which manifest themselves more quickly and more promptly in pulmonary diseases than those of strychnine. One of its earliest ameliorating influences is seen in the lessened amount of cough and expectoration. Another is the relief which it affords to difficult breathing and in quieting the nervous restlessness. There is also a reduction in the accelerated pulse-rate. The alleviation of these symptoms is especially pronounced in those who suffer from chronic bronchitis or asthma. At the same time the patient has a desire for more food, and begins to increase in weight and gain in strength. This tendency to put on flesh seems to be one of the peculiar attributes of strychnine. Thus, I have observed that the hypodermatic administration of this drug daily, in doses of $\frac{1}{24}$ of a grain, other conditions remaining the same, added five pounds in the course of eight days to the weight of a patient suffering from angina pectoris. I have seen the same improvement in other diseases in which this agent was given by the mouth. This power on the part of strychnine to augment bodily weight is really a very important one, inasmuch as it demonstrates that drugs which are exclusively stimulant in their action are also constructive agents in an indirect sense, although, unlike food, they contribute no material whereby the bodily tissues are built up. They act very much like the spur or the whip does on a lazy horse. They enhance molecular or vital activity, and in doing this they cause the tissue-cells to assimilate and to appropriate an increased amount of reserve nutritive material.

Dose of Strychnine.

The amount of strychnine which is given is of more importance than the mere giving of the drug itself. I have long been convinced that in the great majority of diseases strychnine is inert on account of the diminutiveness of the dose in which it is commonly administered, and that to secure the greatest and best possible advantage, it is necessary to push it to the point of therapeutic tolerance. From this it is not to be inferred that the patient should be exposed to the risk of strychnine-poisoning, but that the constitution should be slowly impressed with the influence of the drug until there is developed a heightened reflex irritability and general restlessness, or until brilliant light or loud sounds produce a painful sensation in the eyes and ears, or until diarrhea occurs. When these symptoms begin to show themselves the quantity of the drug must be reduced, either by diminishing the dose or by giving the dose which was previously given at longer intervals. The same dose which develops toxic symptoms at one time may, however, subsequently be given with perfect impunity—showing that instead of being cumulative, as it is generally supposed to be, it establishes a tolerance for itself.

So far as my experience goes, the best results are obtained from strychnine by beginning with doses of $\frac{1}{32}$ of a grain four times a day, and although this may seem to be a large amount to start with, practically it is well borne in most cases. Indeed, it seems as if most of those who are suffering from asthma, bronchitis, and kindred diseases, bear larger doses of this drug than those who suffer from other general affections. After finding that this dose agrees, I give it for two weeks, and then begin to increase it $\frac{1}{8}$ of a grain each week, until the patient begins to manifest some physiologic disturbance due to its action. In some cases this does not occur until $\frac{1}{7}$ or $\frac{1}{6}$ of a grain, or even a larger dose is given, four times a day. My usual way of administering strychnine in pulmonary diseases is to combine it with the following drugs, which I believe have the power of enhancing its action and of meeting some collateral indications in these cases.

℞.—Phenacetini, Acetanilidi, Quininæ sulph. . . āā gr. xxxij.
Pulv. capsici . . . . gr. v.
Ammon. chlorid. . . . ʒj.
Strychninæ sulph. . . . gr. j.
Atropinæ sulph. . . . gr. $\frac{1}{25}$.—M.
Ft. capsulas no. xxxij.
Sig.—One capsule four times a day.

This combination may be modified. If there is much fever the doses of phenacetin and acetanilid may be doubled or trebled, and in case of marked sweating the atropine may also be increased. In pulmonary diseases brought on by the abuse of alcohol the dose of capsicum may be largely augmented with benefit.

The Special Application of Strychnine.

The special application of strychnine to individual pulmonary diseases will now be considered in the fol-

lowing order: (1) asthma; (2) bronchitis; (3) emphysema; (4) croupous pneumonia; and (5) pulmonary consumption.

ASTHMA.—In the treatment of asthma it is advisable to begin with $\frac{1}{30}$ of a grain hypodermatically, and on account of the nocturnal nature of the disease, if possible, give the injection in the evening, so that its influence may fully extend to the time of the attack. In addition to this, give from $\frac{1}{32}$ to $\frac{1}{30}$ of a grain of the same drug four times a day in connection with the phenacetin, etc., in the aforementioned capsules, or the same dose may be administered with half a dram each of syrup of hydriodic acid and syrup of the hypophosphites, four times a day. Increase the dose of strychnine gradually, both in the hypodermatic injections and in its administration by the mouth. As much as $\frac{1}{20}$ of a grain is easily borne by most asthmatics, and the injections should be repeated every, or every other, evening until the attacks disappear. If the attack is very stubborn, and the patient has lost a great deal of rest, add $\frac{1}{20}$ of a grain of morphine to the first few evening injections. Due attention, must of course, be given to food, diathesis, state of the excretions, rest, well-regulated exercise, etc., in all cases of this kind.

CHRONIC BRONCHITIS.—In this disease strychnine is strongly indicated and always used with advantage. This holds as well in that form which is idiopathic or primary as it does in that which is secondary to some cardiac disorder. As a rule, there is less urgency for relief in this disease than there is in asthma, and hence the hypodermatic administration of strychnine is less imperative. In the primary form in adults, commence the treatment by giving $\frac{1}{32}$ of a grain four times a day with syrup of the hypophosphites and syrup of hydriodic acid, and slowly increase to $\frac{1}{20}$ or $\frac{1}{16}$ of a grain. In cardiac or secondary bronchitis five drops of the tincture of digitalis may be added to each dose of strychnine. This is not essential, however, for cardiac bronchitis, especially when associated with irregularity of the heart's action, will do remarkably well under the strychnine and syrups alone. Of course it is always of the greatest importance to unload the portal circulation by free catharsis with calomel at the very outset. When the expectoration is profuse, combine the strychnine with phenacetin, quinine, atropine, capsicum, and ammonium chlorid. In the chronic bronchitis of children more than eight years old, begin with $\frac{1}{40}$ of a grain of strychnine with the syrups, three times a day, and gradually increase to $\frac{1}{32}$ of a grain at the same intervals. In children it is especially advisable to apply a weak liniment composed of croton oil and sweet oil, one part of the former to five parts of the latter, well rubbed in the chest, morning and evening, until a crop of fine pustules is produced.

EMPHYSEMA.—This disease is usually secondary to asthma, chronic bronchitis, pneumonia, or phthisis, and consists of a more or less permanent dilatation of the pulmonary air-cells on account of a loss of contractility or elasticity of the walls of these structures. Although we know nothing of the distribution of nerve-fibers to the vesicular parts of the lungs, or whether strychnine has the power of contracting or of giving tone to the distended vesicles, it is quite certain that this agent has a wonderful ameliorating influence on this morbid condition—perhaps more by relieving the concomitant bronchitis, by fortifying the parts less seriously implicated and by increasing the constitutional vigor, than by any direct action. In the beginning of the treatment $\frac{1}{32}$ of a grain should be given to adults four times a day, and this should be progressively increased until a decided impression is made on the patient. If the dyspnea is very pronounced, this dose may be reinforced by an injection of $\frac{1}{30}$ of a grain of the same drug daily or every other day.

CROUPOUS PNEUMONIA.—The employment of strychnine in large doses in the treatment of croupous pneumonia is, so far as I know, chiefly owing to the clinical researches of Dr. Brunton, which, if I remember rightly, were published in the *British Medical Journal* about eighteen months ago. At any rate, his experience led me to test it, and I can fully confirm his favorable opinion of its action. My method of administering this drug in croupous pneumonia is as follows: Immediately after seeing an adult case, I give $\frac{1}{30}$ of a grain hypodermatically, and $\frac{1}{30}$ of a grain by the mouth, alternately every three hours. The hypodermatic injections, together with the internal administration, are continued until decided restlessness begins to be shown by the patient, which usually occurs on the fourth or fifth day of the treatment. In some cases this appears earlier. Old alcoholics who suffer from this disease bear even larger doses with great benefit. It is worthy of remark, too, that strychnine has a sedative influence on the restlessness, delirium, picking at the bed-clothing, etc., which are caused by the disease. Care must, therefore, be exercised so that these symptoms are not mistaken for the toxic action of the drug. Strychnine, in connection with the external application of ice in rubber bags, and nutritious food, has given me most unexceptionable results in the treatment of croupous pneumonia, for a record of which I beg to refer to my two communications on this subject, which were published in THE MEDICAL NEWS for September 24, 1892, and January 21, 1893. Since that time I have adopted the method in other cases, and have collected quite a number of cases from other practitioners who have been kind enough to test it, all of which I shall prepare for publication at an early day. Strychnine is also very serviceable during convalescence from pneumonia, in combination with the syrup of hypophosphites and syrup of hydriodic acid, as follows:

℞.—Strychninæ sulph. . . . gr. 1 or 1⅛.
Syr. acidi hydriodici. } . āā f℥ij.—M.
Syr. hypophosphit. }

Sig.—One teaspoonful four times daily.

PULMONARY PHTHISIS.—Strychnine is no less valuable in phthisis than it is in any of the diseases in which its action has been discussed this evening, although its effects may be less apparent because it is given in a disease which is essentially chronic in its nature and is less impressible than are acute or functional diseases. Nevertheless I regard it as an indispensable agent in the treatment of this affection, and almost invariably administer $\frac{1}{32}$ of a grain at the outset, in combination with phenacetin, acetanilid, etc. (see composition of capsule, page 92), and, as has already been stated, after the first two weeks increase the dose gradually until the limit of its physiologic action is reached. The quantity of the other ingredients in the capsule remains about the same

except in the case of phenacetin and acetanilid, which are increased or diminished according to the degree of fever present. I may as well say that these two agents are not used here for the sole purpose of subduing the abnormal temperature, but I regard them as most useful supporting agents to the nervous system, and as being capable of enhancing the action of strychnine. I administer them, therefore, when fever is absent, although, as already intimated, in smaller doses than when fever is present. Hence, at the end of a course of three months' treatment of a case of phthisis, with fever of about 100° or 101° in the evening, the probable composition of the capsule will be the following:

℞.—Phenacetini } Acetanilidi }	. . .	āā ʒjss.
Quininæ sulphat.	. . .	gr. xxxij.
Pulv. capsici.	. . .	gr. v.
Ammon. chlorid.	. . .	ʒj.
Strychninæ sulphat.	. . .	gr. ijss.
Atropinæ sulphat.	. . .	gr. $\frac{1}{25}$.—M.

Ft. capsulas no. xxxij.

Sig.—One capsule four times daily.

If fever is practically absent at that period, then a grain each of phenacetin and acetanilid is given, but the quantity of strychnine, as indicated in the foregoing capsule, is maintained. Phenacetin and acetanilid are believed to be injurious when given continuously for a long time, but of this, so far as I am able to judge from gross appearances, I have seen no evidence, even after administering them in large doses to the same individual for a period extending over a year. The most marked influence which follows the administration of this combination in the way described is seen in the diminution of cough and expectoration, in the increase of appetite and strength. In cases of alcoholic phthisis it is necessary to give the strychnine in larger doses than in non-alcoholics, and also increase it progressively. These patients also tolerate inordinate doses of capsicum with great benefit.

In connection with this internal medication it is, of course, understood that in order to succeed it must go hand-in-hand with well-regulated rest, nutritious food, pneumatic and electric treatment, sun-baths, massage, etc. Pulmonary phthisis is a complex constitutional and local disease, the cure of which is not vested in the influence of a specific agent, but in the application of material and forces which tend to augment and enhance the vital resistance of the body to disease.

LOCALIZATION IN DISEASES OF THE SPINAL CORD.[1]

BY FRANK PARSONS NORBURY, M.D.,
OF JACKSONVILLE, ILL.,
LATE ASSISTANT PHYSICIAN, ILLINOIS CENTRAL HOSPITAL FOR THE INSANE, JACKSONVILLE, ILL.; LECTURER ON NERVOUS AND MENTAL DISEASES, KEOKUK MEDICAL COLLEGE, KEOKUK, IOWA; FORMERLY RESIDENT PHYSICIAN, PENNSYLVANIA INSTITUTION FOR FEEBLE-MINDED CHILDREN, ELWYN, PA.

THE clinical study of diseases of the spinal cord has been given new impulse and placed upon a reliable scientific basis by the establishment of the principles of localization. Lesions can now be definitely estimated, and their importance properly assigned. To work out fully their extent, whether in the center or periphery of the cord, or limited to its columns, requires thorough acquaintance with the anatomy and physiology of the cord. Localization is but the correct interpretation of symptoms—motor, sensory, reflex, vasomotor, and trophic—arising in any case of spinal disease. It is to be noted that most diseases of the spinal cord are limited in area, and may involve but one segment or spinal unit. In actual disease, however, even if incipient, more than one segment is usually affected.

The motor symptom most prominent in spinal disease is diminished function or paralysis, although we do have symptoms of increased function, as shown in spasms cramps, and rigidity.

Paralysis of spinal origin may be caused by two distinct lesions: first, when voluntary impulses from the brain to the spinal motor centers are cut off, as in compression; secondly, when the spinal motor centers are destroyed (Starr), as in acute anterior poliomyelitis. The first type is not followed by atrophy, and the electric reaction is normal, while in the second, the paralysis is followed by more or less degenerative atrophy, and the electric reaction of degeneration is marked. Starr emphasizes the importance of separating these two forms of paralysis, because the line of treatment is determined by the condition found. In the first type surgical treatment may remove the cause of paralysis, while in the second nothing can be done.

By the use of electricity we can estimate the degree and distribution of the paralysis, and in this way assist in localizing the lesion. The diagnostic uses of electricity are, therefore, important, and the general rule of Bramwell should be borne in mind, viz.: "When the nutritive condition of muscles and nerves is not profoundly altered—that is, when the trophic-nerve nuclei, the motor nerves, and motor-nerve endings are healthy—the electric alterations are merely quantitative; when, on the contrary, the trophic-nerve nuclei are destroyed, when the trophic-nerve influence is shut off from the muscles by severe lesions of the peripheral nerves, when, in short, the peripheral motor nerves and motor-nerve endings are degenerated, qualitative alterations in the electric reactions, to which the term *the reaction of degeneration* has been applied by Erb, appear."

During the past week I met a case in which the alterations of degeneration, while present, yet required considerable time to work out their extent, and to localize the lesion, thus emphasizing the fact that it is only by observing the muscles, or groups of muscles, thus affected that we can localize the lesion. We must also call to our assistance the very valuable table of Starr, which is to be found in all recent works on diseases of the nervous system.

The sensory symptoms are localized by a study of the distribution of the posterior nerve-fibers and the character of the alterations of sensibility, such as temperature-perception, pain, anesthesia, hyperesthesia, etc., by means calculated to show the impairment of functions in the sensitive areas to be investigated.

The ability to localize sensibility depends greatly on the thoroughness of the tests used. "The point of chief

[1] Read before the Tri-State Medical Society, Keokuk, Iowa, April 4, 1893.

importance in testing sensation is to find some part of the patient's body which is unaffected, and with this part as a standard, to compare affected parts" (Starr). The sensory functions of the individual segments of the cord have been pretty thoroughly determined, so that by defining the area of surface affected we can determine the localization of the lesion.

In the study of the localized functions of the cord the level of origin of the nerves, their point of exit in relation to the spinous processes, and their final distribution, are of paramount importance. The diagram of Gowers, to be found in all standard works, shows the relationship of the vertebral and spinal segments and spinal nerves. The spinal nerves have their exit lower through the spinous processes than they arise in the cord, and as we descend the cord these lengths of the nerves increase before passing out of the canal, so that when we reach the end of the cord we find quite a bunch of nerves forming the cauda equina. We must bear in mind, therefore, that the lumbar nerves are not opposite the lumbar vertebræ, nor, in fact, are any of the spinal nerves directly opposite the vertebræ of the same name. This fact is of great importance in surgical diagnosis. Spinal lesions are generally bilateral, and especially so in sensory disturbances, although in what is termed Brown-Séquard's paralysis we find "paralysis of motion and muscle-sense on the same side as the lesion, while sensibility is paralyzed on the opposite side, pain and temperature being especially affected." Hyperesthesia and increased reflex action are noted on the side of the lesion.

Other primary considerations in the localization-study of diseases of the spinal cord are the reflexes. They show the condition of portions of the segment through which the reflex passes. To insure reflex action requires that the sensory or efferent fibers be intact, the ganglion-cell perfect, and the afferent or motor fibers preserved; this combination constitutes the reflex arc, and any interference with one or more of these essential elements, affects reflex action. Disease may destroy the lateral columns and posterio-internal columns without affecting reflex action. The reflex system of the spinal cord is made up of a series of these arcs or loops, and disease may affect one or more of them, being manifested either in increased or diminished action. Disease may not be indicated by the absence of a reflex, for through an idiosyncrasy in the physiologic make-up of a person it may be absent; again, disease outside of the cord may affect reflex action. Disease affecting special portions of the cord, as in locomotor ataxia, will destroy reflex action.

Excessive or increased reflex action is caused by disease that increases the irritability, and, consequently, diminishes the specific resistance of the arc in any part of its course, as excitability of gray matter from adjacent inflammatory disturbances, and then diseases which arrest conduction, as in diseases of the lateral columns, where both superficial and deep reflexes are affected.

The localization of reflex disturbances enables us to confirm motor and sensory symptoms. The superficial reflexes are the plantar, gluteal, cremasteric, abdominal, epigastric, and interscapular, each having local significance and importance.

The interscapular reflex embraces the seventh and eighth cervical and the first and second dorsal segments; the epigastric, the fourth to the seventh dorsal, inclusive; the abdominal, the eighth to the twelfth dorsal, inclusive; the cremasteric, the first to the third lumbar; the gluteal, the fourth and fifth lumbar; and the plantar, the first to the third sacral. These reflexes are obtained by gently irritating the skin with the point of a sharp instrument or with the finger.

The important deep reflexes are the patellar tendon-reflex and the ankle-clonus. The patellar tendon-reflex is obtained by striking the ligamentum patellæ while the knee is semi-flexed, or, as Buzzard recommends, by having the patient, who is seated, plant his foot firmly down at such a distance that the leg forms a little more than a right angle with the thigh, whilst the observer rests the palm of his left hand upon the patient's thigh, and with the right strikes the ligamentum patellæ about one-eighth of an inch below the knee-cap. The quadriceps muscle can be felt, and can be seen to contract more or less vigorously in response. If the patient is in bed, the knee should be flexed and the heel held firmly down upon the bedding whilst the blow is struck. The quadriceps will be seen to contract. If the phenomenon be absent, we must then endeavor to locate the interruption in the arc and ascertain its cause. If the patient can walk freely, and can flex and extend the leg with vigor, we may exclude the motor side of the arc. The most conspicuous illustration of a flaw on the sensory side is furnished by tabes dorsalis.

Trophic disturbances will cut off reflex action, as the seat of this influence is known to be in the large ganglion-cells which lie in the anterior horn. Interruption in this case may exist either in the anterior root outside the cord, the short portion within the cord, or in the anterior horn of gray matter itself.

As regards the second of these possibilities, nothing is certainly known that will enable us to localize the lesion in that particular portion of the anterior root.

Ankle-clonus is only present in case of disease, and it signifies that from some cause the inhibitory influence of the higher centers is no longer normally exercised. The natural impulses from above are somewhere interfered with. Sclerosis invading the antero-lateral columns interferes with nervous impulses travelling down this path, and ankle-clonus is marked. Changes in these columns, of several months' duration, are usually permanent, and so excessive a reflex as is represented in ankle-clonus means structural change that will be unalterable.

In spastic functional paraplegia we elicit ankle-clonus, but this is not necessarily an indication of chronicity, and in hysteria[1] we will find increased tendon-reflex. In the latter the cerebral influence is considerable, and this Buzzard thinks is sufficient to inhibit the nervous impulses reaching the spinal centers. The absence, then, of impulses downward through the lateral columns seems to result in an effect upon the tendon-reflex very similar to that occasioned by the resistance to their propagation through the columns which is interposed by the structural changes occurring in sclerosis.

[1] I use this term "hysteria" as differing from functional, according to Bastian, in his recent valuable contribution to the study of hysterical and functional paralysis.

The organic reflexes, viz., the vesical, rectal, and sexual, offer special and important considerations in the study of diseases of the spinal cord as factors in localization. They belong to the independent functions of the cord, and their action is not concerned in volition. Disease may affect each center separately, but usually they are simultaneously affected because of their location. These centers are situated in the lower portion of the cord, the genital centers reaching from the first to the third sacral segment, inclusive. The bladder and rectal centers extend from the fourth to the fifth sacral segment, inclusive. Starr says that they are adjacent to one another, and the sphincters are uncontrollable when the lesion involves the lower three sacral segments. The center then is probably in the two lower. Disease may affect these centers by excessive stimulation, and as a result both the bladder and rectum fail to act normally.

We may have incontinence or retention of urine: incontinence when there is excessive stimulation of the nerves, as in cystitis, and the presence of a foreign body in the bladder, or when, as in children, it is due to spasm of the bladder, or lack of tone of the sphincter. Retention is the result of paralysis, and localizes the lesion in the lumbar region. The rectum is similarly affected. We often note in spinal disease localized in the dorsal region that defecation and micturition are affected; that is, the functions are performed with normal regularity, but the control of the will over these functions is lost. I saw recently such a case. The bladder and rectal centers were unaffected, because they were not included in the diseased area, but, as the patient expressed it, he "could not hold his water, or control his passages," because of dorsal disease.

The sexual reflex controls erection and ejaculation, and is an important one. Impotence is due to destruction of this center, or to inhibition of it, by reason of general spinal weakness. By reason of the intimate nervous connection of the genito-urinary organs with the cerebro-spinal system, we may have nervous disturbances growing out of this reflex arc. The sensory portion of the arc is enormous; the conducting cords which attach the genital organs to the centers are highly developed.

Robinson says that "branches from the second and fourth sacral and the entire third sacral segment go to make up the enormous nerve-supply for such small organs as the genitals." The bladder and rectum also receive branches from this same supply, so that we find the action of the bladder, rectum, and genitals wonderfully harmonious.

In woman we note this dominating influence more than in man, for the great and complicated nerve-supply to the female genitals accounts for the danger of nervous complications and its stubborn pathology. Robinson says: "It may be laid down as a general proposition that the viscera have their normal function in rhythm and the disturbance of the rhythm is what induces disease." It may also be said that the main pathology of the sympathetic is reflex action from some distant viscus. All have noticed the close nervous connection of the genitals with the nervous system. In woman uterine disorders occasion a thousand and one ills, while in man the reflex irritation of disease completely upsets him. The whole spinal disorder is often purely reflex, and we must not overlook the rectum and genito-urinary organs as aids to diagnosis and localization.

Let us now outline the motor and sensory symptoms to be noticed in focal disease of the cord in various regions.

In the cervical region lesions above the fourth segment cause death by involvement of the phrenic nerve. Upper-arm motor symptoms, with disturbances of sensation of the entire trunk and arm, characterize involvement of the fifth and sixth cervical segments. Lower-arm motor symptoms, with disturbances of sensation of the trunk and inner surface of the arm and portions of the hand, denote involvement of the seventh and eighth cervical segments. The dorsal region gives the "girdle sensation" when the lesion is transverse, and this locates the level and determines the segment involved. The various levels are well outlined—the third rib corresponds to the third segment, the nipple to the fourth, while the sixth and seventh are regionally located by the distribution of nerves to the epigastrium; the tenth segment distribution is near the umbilicus, etc. The motor symptoms to be noticed are paralysis of the intercostal muscles in the upper dorsal lesions and the abdominal muscles in the lower.

Lumbar lesions may or may not involve the entire lumbar enlargement. When total anesthesia of the legs, thighs, and buttocks prevails, then the entire lumbar segment is involved. But if the upper portion is alone involved, then we find anesthesia of the thigh, outer portions of the groin, part of the scrotum, and paralysis of the muscles which flex the thigh, including also the sartorius muscle.

If the middle lumbar segments are alone involved, then we have anesthesia of the thigh and paralysis of the muscles which extend the knee and adduct the thigh. The sacral region is indicated by paralysis of the bladder and rectum in lesions extending as high as the fifth sacral segment. When the fourth and fifth sacral segments are involved we have paralysis of the peroneal muscles, and muscles of the leg and foot when higher. Herter says the area of anesthesia in sacral lesions is characteristic, extending from slight anesthesia about the coccyx in the fifth sacral involvement to the saddle-shaped area of the fourth segment, while in the upper segments strips of anesthesia on the back of the thigh, leg, and ankle to the sole and dorsum of the foot are noticed. Lesions of the cauda equina are diagnosticated by outlining the anesthesia, looking for deformities, and in the examination of the cord for purely cord symptoms.

Lesions in this region are due to pressure from fracture of the spine or dislocation, etc. As these cases are of surgical importance, localization should be carefully observed, so that the lesion may be removed. I recently saw a gentleman who had a fractured coccyx, causing pressure on the cauda equina. For eight years he went from sanitarium to sanitarium, seeking relief for spinal irritation and neurasthesia. He did not find relief until his case was found to be a surgical one; operation relieved him.

Again, I would call your attention to Starr's table in localizing the lesions, for by it and with the use of

electricity you can closely define regional location of the lesions in spinal-cord disease.

CLINICAL MEMORANDA.

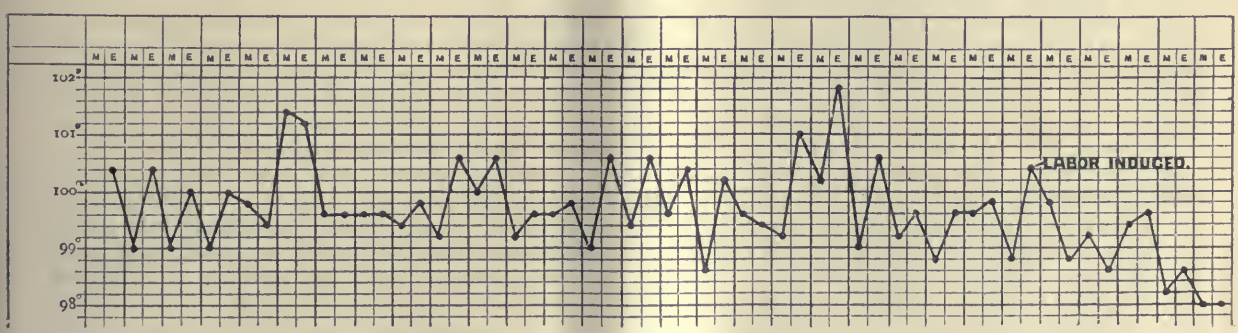
LONG-CONTINUED HEMORRHAGE IN THE LATTER HALF OF PREGNANCY, DUE TO DETACHMENT OF A NORMALLY SITUATED PLACENTA, AND ACCOMPANIED BY SEPTIC INTOXICATION: WITH A REPORT OF TWO CASES.

BY BARTON COOKE HIRST, M.D.,
OF PHILADELPHIA,
PROFESSOR OF OBSTETRICS, UNIVERSITY OF PENNSYLVANIA.

WHEN the practitioner thinks of accidental hemorrhage he usually has in mind a concealed hemorrhage of a very dangerous character, or possibly, a frank outpour of blood, soon ceasing spontaneously or followed by active uterine contraction, the explusion of the uterine contents, and the cessation of bleeding when the placenta is wholly detached and expelled. Premature detachment of the placenta is, indeed, commonly manifested in one of these two ways. Rarely, however, the detachment of a portion of a normally situated placenta is followed by a steady leakage of blood, continuing for weeks, resulting in the formation of a large blood-clot between the layers of the decidua vera, reaching from the lower margin of the placenta to the internal os, as the blood makes its way slowly from the site of hemorrhage to the orifice of the womb. This clot soon begins to undergo a slow decomposition; the products of this process are absorbed, and the woman develops a septic fever, which continues till the uterus is emptied. It is not likely that the general practitioner would be prepared for such cases unless he had happened to see and recognize one, for the text-books in common use among us take no account of them. The two examples here reported, occurring in my practice within the past year, demonstrate, however, the possibility of their occurrence:

CASE I.—I was called to a neighboring State some months ago to see a pregnant woman about six months advanced, who had been bleeding profusely from the genital passages for two or three weeks. The patient was profoundly reduced by the unceasing loss of blood, and when I saw her she had considerable fever, which had probably existed for some time. The physician in charge supposed that the blood was oozing from the cervix itself, and had consequently been painting the vaginal portion with Monsel's solution—naturally without success. An examination threw no light upon the nature of the hemorrhage. The os was slightly patulous, and the child was still alive. With the idea that there was a prematurely detached placenta, and in view of the woman's alarming condition, it was decided to terminate pregnancy without delay. On extracting the fetus, with its appendages, it was found from the tear in the membranes that the placenta had been attached at the fundus. Clinging to about a quarter of its maternal surface was a flattened mass of clotted blood, very dark in color and as firm in consistency as liver. It extended along the membranes to and beyond their point of rupture, the whole making a very large clot. The patient had symptoms of septicemia for a time after delivery, but ultimately recovered.

CASE II.—A. C., a domestic, was admitted to the Philadelphia Hospital in the sixth month of pregnancy. Two weeks before admission she had begun to bleed from the vagina without ascertainable cause. The hemorrhage continued without intermission and in increasing amount, so that she was compelled to go to bed, and thus came to the hospital. She was found to have fever,



M E M E M E

ceeded to evacuate the uterus, although the fetus was still alive. The placenta was attached at the fundus. About one-eighth of its surface had obviously become detached some time before (shown by degeneration). To this margin was attached, as in the first case, a long, flat mass of firmly clotted blood, undergoing decomposition. The fever subsided a day or two after delivery, and the woman made a good recovery.

A surprising feature in these cases is the continuance of pregnancy in spite of a partially detached placenta and a huge mass of decomposing blood-clot lying between the membranes and the uterine wall. The appropriate treatment is undoubtedly the evacuation of the uterus. In the first case this was delayed too long, and the patient made a narrow escape. In the second case, I was curious to see how long pregnancy could continue in spite of such unfavorable conditions. I waited, therefore, as long as I dared, half expecting a spontaneous evacuation of the womb at any time, and keeping the patient under constant supervision, prepared to interfere at once should threatening symptoms develop.

OF PHILADELPHIA,
PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS IN THE PHILADELPHIA POLYCLINIC; ONE OF THE PHYSICIANS TO THE PHILADELPHIA HOSPITAL, ETC.

III.

CODEINE SULPHATE.

CURRENT literature would seem to indicate that resort to codeine is more common in Europe than in America; yet those American physicians who have had large experience with both morphine and codeine agree with their trans-Atlantic colleagues in preferring the latter under many circumstances. The dose of codeine laid down in most of the text-books is too large. While the drug may safely be given, if necessary, in doses of from two to six grains, on the basis that its narcotic power is but one-fourth that of morphine, yet, in medicinal usage its dose need not ordinarily be greater than would be the dose of morphine used in the same conditions. I frequently give $\frac{1}{16}$ grain, and rarely exceed $\frac{1}{2}$ grain. The drug should, however, be repeated much more frequently than would be safe with morphine; and one of the advantages of codeine over morphine lies in this safety of frequent repetition. The greatest advantage of codeine over morphine, however, lies in the facts that it is less likely to excite a morbid drug-habit; and that in the unfortunate cases in which its long-continued use becomes necessary, it does not give rise to the distressing results that a corresponding use of morphine often entails. It has thus been used in an endeavor to cure the morphine-habit. As compared with morphine, the sedative and hypnotic effects of codeine are greater, its anodyne and narcotic effects less. In addition, it appears from clinical data to have a special influence upon inflammations of serous membranes, and thus to be useful in checking the spread of pleuritis and peritonitis. Its power to diminish the excretion, and presumably the morbid production, of sugar in cases of diabetes mellitus is well established. Upon the normal secretions its effect is less marked than that of morphine, and in moderate doses constipation, dryness of the throat, diminution of urine, and of perspiration, are not usually produced.

In most of the conditions in which morphine is ordinarily employed, except when it is desired to promptly cause sleep or lessen pain by hypodermatic injection, codeine is to be preferred.

When it is considered advisable to add an opiate to a cough mixture, codeine sulphate may be given in doses of from $\frac{1}{16}$ to $\frac{1}{4}$ grain. Thus, in cases of acute or subacute catarrh of the laryngo-tracheo-bronchial tract, in which there is irritability of the inflamed mucous membrane, leading to more frequent cough than is necessary for the expulsion of morbid products, ten or fifteen grains of ammonium chlorid, with from $\frac{1}{12}$ to $\frac{1}{8}$ grain of codeine sulphate, may be given every two, three, or four hours. When a patient, as a busy man, finds it inconvenient to carry a liquid mixture, this prescription may be made into a mass with powdered extract of licorice and acacia, and dispensed in capsule. A little water should be swallowed with or after the capsule. Another quite useful combination in the catarrhal affections of influenza, in cases of ordinary bronchitis, and in cases of broncho-pneumonia due to exposure especially when there is an associated pleuritis, is the following:

Phenol salicylate, or cinchonidine salicylate	from 3 to 5 grains.
Terpin hydrate . .	" 3 to 5 "
Codeine sulphate . .	" $\frac{1}{12}$ to $\frac{1}{8}$ grain.

Mix. Dispense in capsule.

Dose: One capsule with water every two to four hours.

This, or a similar prescription, is likewise beneficial in the "colds," bronchitic, pneumonitic, and pleuritic, that often retard recovery or cause "set-backs" in cases of pulmonary tuberculosis improving, or apparently well, under hygienic and other appropriate treatment. In simple pleurisies and in rheumatic pleurisies the terpin hydrate may be omitted. In the cough of pulmonary tuberculosis and other chronic conditions, when a sedative is indicated, codeine is always preferable to morphine. It is best given alone in tablets of $\frac{1}{8}$ grain each, the frequency of repetition being governed by the effect. Often one tablet at bedtime, or one early in the evening and another at bedtime, will be sufficient.

In acute tuberculosis codeine is a useful palliative. In tuberculosis and other painful affections of the pharynx and larynx, lozenges containing about $\frac{1}{8}$ grain of codeine in fruit-jelly, mallow, Irish or Iceland moss, or other demulcent, are often soothing and anodyne. In some cases cocaine may be added to such a lozenge.

In my own experience, codeine has not been equal to morphine as an analgesic in neuralgia; but on the other hand, when the pain has been traceable to inflammation, whether of nerve structures or other tissues, codeine has seemed the better agent. When used to control pain it should be given in larger doses than have thus far been spoken of, *i. e.*, from $\frac{1}{4}$ to $\frac{1}{2}$ grain, repeated at intervals of from fifteen to thirty minutes, until effective, either in relieving pain or causing sleep, or until four or six grains have been taken.

In the sleeplessness and headache of acute fevers, codeine may be given in doses of from $\frac{1}{2}$ to 2 grains, repeated every half-hour, every hour, or every second

hour, according to indications. If sleep is not produced by six grains, the drug should be abandoned.

In chronic insomnia of various causation, codeine may be employed in the manner advised for acute cases, or small doses may be given during the day, and one or two full doses at night. If its use is determined upon, it should not be abandoned until a sufficiently long trial had proved its ineffectiveness. It produces a sleep more nearly natural than that of morphine, and the after-effects are not unpleasant. Many alienists commend it highly. In the pains of visceral carcinoma and other hopeless affections, it may be tried before resorting to morphine, and will in many cases be found efficient.

In diabetes it is best administered with hydrogen dioxid, and should be given in ascending doses, being maintained at the point which, with least discomfort to the patient, lessens in the greatest degree the excretion of sugar. The determination of this point is a matter of careful observation and discriminating judgment in the individual case; and all the subjective and objective symptoms must be considered. Some patients do fairly well on a grain or two in the twenty-four hours, while others require six or more grains. While life is usually prolonged, and comfort much promoted, we cannot as yet regard the drug as more than a palliative; yet, recovery sometimes takes place apparently under the influence of codeine. Some patients who exhibit idiosyncrasies to morphine can take codeine with impunity, but this is by no means the rule, and inquiry must be made, and due caution exercised.

A CASE OF VOMITING OF PREGNANCY, RESULTING IN THE INDUCTION OF ABORTION.[1]

BY JOHN O. POLAK, M.D.,
OF NEW YORK,
INSTRUCTOR IN CLINICAL OBSTETRICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND IN THE LONG ISLAND COLLEGE HOSPITAL, BROOKLYN.

IN presenting the history of this case, it is not because of anything atypical in its clinical course, but rather to emphasize some of the methods of treatment that may be of value in the management of such cases.

Mrs. J., thirty-five years old, tertipara, bore her first child in 1887, her second in 1890. She menstruated first at fourteen, and has since been regular, the flow lasting four or five days, though small in amount. Great pain preceded and accompanied the flow. The woman was of neurotic temperament. She last menstruated November 27, 1892, the flow lasting three days, and being about normal in amount. A slight show was noticed December 25, 1892, and again January 22, 1893. Upon December 26th, when gestation had progressed about four weeks, nausea and vomiting began and continued to a greater or less extent until March 13, 1893. At no time during this period was solid food taken. The emaciation was rapid and progressive, though for periods of from twelve to twenty-four hours the patient would retain small quantities of liquid food, only to be followed by nausea, retching, or the vomiting of bloody mucus, sometimes bile-stained and containing what appeared to be gangrenous masses. All treatment usual in such cases, such as dietetic measures, cocaine, chloral, argentic oxid, morphine, calomel, cerium oxalate, etc., was used without avail.

On March 5th I was asked to see the patient in consultation. She was emaciated, pale, almost cadaveric in appearance, and very nervous. The pulse was 120, small, though wiry, varying from 130 to 140 under the least excitement. She had been confined to her bed for six weeks, vomiting almost constantly, not only everything that was ingested, but also the mucous secretion of the stomach, which was often streaked with blood, together with the gangrenous masses already spoken of. There was a point of exquisite tenderness in the median line in the epigastrium.

Upon bimanual examination I found a uterine tumor about one and one-half inches above the pubes. The uterus was greatly anteflexed, the cervix softened; the bellying of the lower anterior segment was easily recognized, and the canal was somewhat patulous. Neither subjective nor objective fetal movements had been appreciated, but intermittent uterine contractions could be elicited in the usual manner. After this examination I had no hesitancy in saying that the woman was pregnant, notwithstanding the behavior of her menses. I advised that everything, solids, fluids, etc., be withheld from the stomach, and that rectal alimentation be resorted to. I applied a twenty per cent. cocaine solution freely to the portio vaginalis and within the cervix, at the same time introducing my finger to the os internum, after the method of Copeman. This treatment was rigorously carried out for seven days without success, the patient getting progressively worse. Upon March 12th, with counsel, Dr. Cox induced labor by the introduction of ʒj of sterilized glycerin between the membranes. At 6 P.M. of the same day, pains set in, but were insufficient. The membranes ruptured and the bleeding became annoying, though as yet not dangerous. With each pain there was retching, and oftentimes emesis. By 5 A.M. of March 13th the patient was in such an alarming condition from continued loss of blood that Dr. Donaghue was asked to see the case. He immediately tamponed the vagina tightly with iodoform-gauze, thus relieving the hemorrhage. The woman's temperature at this time was 102.2°, her pulse varying from 145 to 160, and being weak, almost imperceptible, and often intermitting.

At 9.30 A.M. I again met Drs. Cox and Donaghue in consultation. The woman's temperature was now 103°, her pulse 170 and almost imperceptible at the wrist. The respirations were sighing in character; the face was blanched, the eyes fixed, the surface cold. Before undertaking operative measures I injected Oj of a normal salt solution at 100° F. into the rectum, most of which was retained, and ʒiv of the same solution into the loose connective tissue below the clavicle on either side. The pulse almost immediately improved in character and volume. Two hypodermatic injections of ♏xx each of tincture of digitalis were also given.

Then, under chloroform, after thoroughly disinfecting hands, parts, and instruments, I emptied the uterus of a pair of four months' male twins, with one placenta. The uterus and vagina were immediately tamponed with iodoform-gauze to prevent further hemorrhage. The patient was in such a critical condition from acute

[1] Read before the Long Island Medical Society, May 4, 1893.

anemia that hypodermatic injections of digitalis, whiskey, and ammonia were resorted to; she was additionally placed in bed, with the hips elevated, and a pint of normal saline solution at 100° F. was injected into the subcutaneous tissue between the scapulæ. The reaction was prompt and satisfactory. The nausea and vomiting immediately ceased with the evacuation of the uterus, and small quantities of champagne were retained. The convalescence, though slow, was entirely satisfactory under the use of stimulants, tonics, and electricity.

As to the management of these cases, induction of abortion is often resorted to before all other methods have been exhausted. In two other cases in which I was consulted, abortion was contemplated, but the woman was saved by rectal alimentation and the introduction of a solid stick of argentic nitrate into the cervix to the os internum. This plan has been more satisfactory in my hands than Copeman's dilatation or the application of cocaine to the cervix.

In my opinion the vomiting in this case was due to the extreme anteflexion of the uterus and the neurotic temperament of the patient.

An interesting fact first brought to my attention by Dr. King, of Washington, is illustrated in the following history. Mrs. S., twenty years old, pregnant two and one-half months, applied to me for relief from distressing vomiting, which the usual therapeutic methods had failed to check. Upon close questioning I elicited the fact that she was having coition at least three times a week. I placed her upon wine-glassful doses of magnesium citrate, and left, with her promise to abstain from intercourse. The improvement was prompt and marked, so much so that, at the end of a week, feeling perfectly well, she again permitted coition, and the vomiting immediately returned, ceasing at once upon abstinence from that unphysiologic practice.

Since then I have had two marked instances of coition during pregnancy acting as the exciting cause of vomiting.

HYPERTROPHIC RHINITIS, PRODUCING OCULAR ASTHENOPIA.[1]

BY EDWARD J. BERNSTEIN, M.D.,
OF BALTIMORE, MD.

USUALLY the treatment of asthenopia is a matter of very little difficulty to the surgeon, but there are now and again cases that seem to baffle every effort. I write with the object of calling your attention to a frequently overlooked factor in these cases.

The condition *sine qua non* is that the refraction shall have been thoroughly and efficiently estimated and corrected, and yet relief does not follow. In many such cases an intelligent observation of the nares will explain the mystery. We are all aware of the varied reflex neuroses attributed to pathologic conditions of the upper respiratory tract. Hack[2] ten years ago called attention to supra-orbital and ciliary neuralgia due to nasal troubles. He says: "Apparently unimportant lesions, without special symptoms pointing to the nose, may run their course, accompanied by serious reflex neuroses. Certainly all such neuroses do not have their origin in the nose; but when they do, their relief through surgery is most marked." Götze relates that in Rossbach's clinic, among many other reflex symptoms abolished by reduction of the middle turbinates, were ciliary neuralgia and migraine. Schreiber, Bresgen, Schech, Chiari, Heymann have also related many such instances. Grüning says, in reporting on the same subject, that notwithstanding proper attention to the ocular affection, it remained uncured till the nose was treated, even though no special symptom called attention to this organ.

We readily see the intimate connection between these two organs when we remember that the nervous supply of the nasal cavity comes mainly from the nasal branch of the ophthalmic nerve, which, early in its course, as it crosses the optic nerve, gives off two or three small twigs, the long ciliary nerves, which, joining with the short ciliary nerves from the ciliary ganglion, pierce the sclerotic, and running forward between it and the choroid, are distributed to the ciliary muscle and the iris.

In the following cases I have no hesitation in saying that the refractive error was thoroughly corrected, yet the permanent relief only came through reduction of the hypertrophied turbinates. My attention was first directed to this condition by some remarks of Mr. Lennox Browne, made upon a case which he was treating for ciliary neuralgia.

CASE I.—Mrs. M., thirty-two years of age, a pale, nervous woman, with a history of tuberculosis in her family, was sent by her physician for treatment for asthenopia. Any prolonged effort at sewing or reading brought on excessive pain and fainty feelings.

V. = R. E., 6/v? L. E., 6/vi? H. manifest, R. E., + sph. 1.25 D; L. E., + sph. 1.50 D.

The ophthalmoscopic examination (seen with + 1.50 D) showed the fundi normal.

By retinoscopy, under homatropine, I found + sph. 1.50 D.

I estimated the refraction to be as follows:

R. E., + sph. 1. D ⊃ + cyl. 0.25 D, ax. 90° = 6/vi.

L. E., + sph. 0.75 D ⊃ + cyl. 0.75 D, ax. 90° = 6/vi.

I then ordered these lenses, which she wore persistently. In a month she returned, complaining that she had no relief. I went over the examination again, and got the same results. I then reduced the strength of the glasses in various ways, but without any permanently good effect. During the visits the statement was made that she had had some catarrhal troubles some years ago, which had been successfully treated, she said, by Dr. Arnold, now of San Francisco. On examination, the middle turbinated bodies were found firmly impacted between the septum and the outer wall of the nares. On palpation, they were found to be excessively sensitive, and gave her the same pain experienced in prolonged usage of the eyes. She also complained of dryness of the throat. The mucous membrane of the pharynx was in a state of granular degeneration. Cauterization of the turbinates with the electro-cautery and chromic acid and application of Schech's iodin solution to the pharynx soon brought about a change. She now uses her eyes

[1] Read before the Section on Ophthalmology, Otology, and Laryngology of the Maryland Medical and Chirurgical Faculty, April 27, 1893.

[2] Hack: "Reflex Neurosen und Nasenleiden," Berlin. klin. Wochenschr., 1882.

with comfort, wearing convex cylinders only for the refraction error. I may say that no muscular imbalance worthy of correction could be discovered.

Case II.—Mrs. B., thirty-eight years of age, a robust woman, not of a nervous temperament, complained of asthenopia, which had not been successfully treated. On examination, I found mixed astigmatism, and no esophoria or exophoria, but hyperphoria of 2°. Examination showed the discs to be elongated and bounded by a small temporal crescent. The macular reflex was normal, as well as other portions of the background. I ordered:

R. E., + sph. 1. D ⌒ — cyl. 2. D, ax. 80°.
L. E., + sph. 1.25 D ⌒ — cyl. 2.25 D, ax. 80°.

These glasses were worn with greater comfort than she had yet obtained. She returned in three months, saying that although much better, she still did not have absolute comfort. Thinking to correct the hyperphoria, I made the necessary examination, but could not now discover it. I examined the nose and found the same condition of the middle turbinates as in the case first reported, with secondary involvement of the pharynx. These conditions were treated in the usual manner, with absolute relief of all symptoms.

A third case, in the wife of a prominent physician, there was compound hypermetropic astigmatism of one eye and a low degree of simple myopia of the other, has thus far had no relief from any glass I could give her. She has, besides the refractive error, 3° right esophoria and 4° left; but no hyperphoria. The patient is of a very high-strung, nervous temperament, and very little could be accomplished at any one stitting. I examined the nose and found hypertrophic rhinitis and the pharnyx secondarily involved. The slightest touch of the wool-covered probe induced intense pain in the orbital and supra-orbital regions. Treatment of the nose was begun, but was interrupted by an intercurrent attack of illness. There is not a shadow of doubt in my mind that the main cause for her asthenopia will be found in the nasal cavity.

I wish to indorse the conclusions of Dr. de Schweinitz in his article on the subject in The Medical News of April 2, 1892, to which I would refer the reader.

218 W. Franklin St.

MEDICAL PROGRESS.

Successful Unilateral Laryngectomy for Carcinoma.—Monks (*Annals of Surgery*, vol. xviii, No. 1, p. 18) has reported the case of a photographer, thirty-nine years old, who had been hoarse for about a year and presented thickening and redness of the right vocal band, with decided limitation of movement during respiration and phonaton. The man otherwise appeared quite well and strong. There had never been much marked pain in the throat or difficulty in swallowing, and there was no cachexia; neither was there a family history of carcinoma. The growth was apparently confined to one side of the larynx and no enlargement of the cervical glands could be detected. Other measures failing to afford relief, operation was deemed justifiable. Accordingly, a vertical incision was made in the median line, from the hyoid bone to about an inch and a half below the cricoid cartilage; and at right angles to the first, a second incision, upon the right side of the neck, at about the level of the lower border of the thyroid cartilage. After the thyroid and cricoid cartilages on the right side had been laid bare the adjacent right half of the back of the cricoid was separated from the anterior wall of the esophagus, so that after the operation was finished the esophageal wall might be left intact as high as possible, and the liability to regurgitation of food diminished. The trachea was opened at the lowest part of the wound, just below the cricoid cartilage, and a large-sized silver tracheotomy-tube inserted. The whole larynx was then split in front, in the median line, and the two halves held apart while gauze was packed firmly into the lowest part of the cavity upon the tracheotomy-tube. The entire right half of the larynx was now removed, the incisions beginning from below. The right half of the trachea was first divided just below the cricoid cartilage; then, with the knife within the larynx, the posterior part of the cricoid cartilage was split vertically in the median line. The thyroid cartilage was next carefully separated from its attachments to the soft parts behind and the thyro-hyoid membrane was divided. Lastly, the superior cornu of the thyroid cartilage was pulled down and excised. In this way the entire right half of the larynx was removed, including one-half of the thyroid and cricoid cartilages, the crico-thyroid membrane, the right arytenoid cartilage, the right vocal band and other soft parts. As much as possible of the epiglottis was permitted to remain. A portion of the growth, which had extended across the median line in front, was additionally removed. Through the upper part of the wound, which communicated with the pharynx and esophagus, a large-sized soft-rubber stomach-tube was introduced well down into the esophagus. Around the tube iodoform-gauze was packed and the edges of skin approximated by silk sutures. Histologic examination of the specimen disclosed the structure of epithelioma. After the lapse of twenty-four hours a catheter was substituted for the stomach-tube in the esophagus, liquid nourishment being thus administered. A glass tube, surrounded by an inflated rubber jacket, was likewise substituted for the silver tube in the trachea. This was removed permanently on the fifth day. On the ninth day bits of beefsteak were chewed and swallowed with evident relish, but the catheter was continued for liquids. On the tenth day the patient sat up in a chair for a while, and was able to speak in a whisper by closing the opening in the neck. Subsequently, as the opening manifested a tendency to close, an ordinary tube was placed in the tracheal wound. Soon after leaving the hospital the patient was able to swallow liquids without the presence of the tube and without regurgitation, by exercising slight pressure upon the opening in the esophagus. The patient was well a year after the operation and engaged in his previous occupation. The tube was worn constantly, being held in place by tapes, and its outer opening closed by a cork.

Nocturnal Laryngeal Spasm in an Adult.—Herschell (*Lancet*, No. 3637, p. 1129) has reported the case of a literary man, thirty-six old, of markedly neurasthenic temperament, who for eighteen months had suffered from attacks of spasm of the larynx at night. At first these occurred about twice a week, on some nights two attacks taking place. Under appropriate treatment the

attacks ceased for a time, but returned upon relaxation of hygienic measures. The attacks usually occurred after late dinners and over-indulgence in cigars. They set in about 2 o'clock in the morning, when the man is awakened with a sense of suffocation, from spasm of the larynx, which prevents inspiration. This continues for a few seconds, when the spasm partially relaxes and air is drawn into the larynx with a crowing sound. After nearly a minute the spasm entirely relaxes, but the larynx feels sore and uncomfortable for an hour or two. During the attack the heart beats violently, while afterward the stomach is found tympanitic and distended. Eructation of gas is followed by relief and brings the attack to an end. Often there appears a spasmodic condition of the orifices of the stomach, which prevents the expulsion of the flatus upward or downward. There was no evidence of disease of the heart, vessels, or nervous system.

Parotiditis Complicated by Orchitis, Prostatitis, and Hemoptysis.—COMBY (*L' Union Médicale*, No. 61, p. 725) has reported the case of a gardener, twenty-nine years old, who, after having worked all day in a hot-house, was seized at night with a chill; the right testicle was noted to be swollen, red, heavy, and painful. During the night there occurred sweats, with headache, pain in the back and in the extremities, so that sleep was prevented. There was also evidence of the existence a mild prostatitis. On the following day delirium set in, and a day later still painful swelling appeared in both parotid regions. There were fever and dyspnea, and in the midst of a paroxysm of coughing, profuse hemoptysis occurred. Improvement now soon set in, and in a short time the man was convalescent. Examination of the chest failed to disclose evidence of organic disease; neither did the urine present any abnormality. The treatment employed consisted in the administration of quinine sulphate, purgation, the application of emollient compresses to the testicle, and a milk-diet.

Ulceration of the Mouth, of Tabetic Origin.—At a recent meeting of the Paris Society for Dermatology and Syphilography, HUDELO (*Internat. klin. Rundschau*, 1893, No. 25, p. 942) demonstrated a tabetic who presented two areas of ulceration of the mouth corresponding with the left inferior maxillary nerve and the right superior maxillary nerve. The affection had set in a year previously, and began with a painless loss of the teeth, after which the ulcers formed. There was nothing in the family history to explain the occurrence; there was also no history of phosphorus-poisoning; and, although the man had had syphilis, the ulcers did not present the appearances or pursue the course of syphilitic lesions. The ulceration was considered as related to the posterior sclerosis and to be dependent upon an inflammation of the fifth pair of cranial nerves. The skin of the face and the mucous membrane of the mouth were anesthetic.

THERAPEUTIC NOTES.

The Treatment of Inebriety.—At the Twelfth Congress for Internal Medicine, recently held at Wiesbaden, SMITH (Supplement to *Centralbl. f. klin. Medicin*, 1893, No. 25, p. 90) pointed out that the stage at which chronic alcoholism usually comes under the observation of the physician presents two distinct features: (1) A psychic degeneration and depravity, affecting the character, with an extinction of all energy, so that it is impossible for the victim, from his own resources, to rid himself of his condition—inebriety proper; and (2) a series of organic and systemic changes engendered by, but not peculiar to, the alcoholic poison, and the symptoms of which are referable to demonstrable pathologic changes. In view of the psychic condition, it is essential that the patient be placed in an institution devoted solely to the treatment of inebriety. Such an establishment should be situated in the country and isolated from all external communication. It should be under the care of a physician, in whose family the use of alcohol in any form should be rigidly proscribed. There should be no actual restraint, but the most vigilant supervision should be exercised. The institution should be equipped with apparatus for Swedish resistance gymnastics, and opportunities should be afforded for light and useful occupation, such as wood-turning. To be efficient and permanent, the treatment must be continued for a period of from six to twelve months, and in cases of periodic inebriety and other severe varieties for eighteen months. Of the whole number of cases under treatment at Marbach 30 per cent. were cured; of those that remained under treatment for more than six months the proportion of recoveries was 80 per cent. The essential element of treatment is immediate and rigid abstinence. Should manifestations of delirium and collapse appear camphor should be given. After several months of treatment the character of the patient will have changed for the better. Upon dismissal, his future associations should receive thoughtful consideration. Such incurable conditions as alcoholic dementia, alcoholic paranoia, and profound alcoholic mania will necessitate detention in an insane asylum, as well as such cases in which the alcoholism is but a manifestation of moral irresponsibility. Among the curable conditions in which degenerative changes in the central nervous system have taken place may be included alcoholic melancholia, pseudo-paralysis, and pseudo-tabes. Epilepsy and periodic inebriety, however, require treatment of especially long duration.

MEDICAL MEN IN UNIVERSITY SETTLEMENTS.

THE United States Department of Labor is investigating the condition of the slums of Chicago. Officially the term "slums of Chicago" is applied to about a half a square mile of the city, bounded by State, Twelfth, Halsted, and Polk Streets. The investigation of this section includes a plan made to a scale of every floor of every tenement and inhabited building, and a thorough census of the inhabitants themselves. This district has been found to contain 16,000 residents, and the plans show four bath-tubs. Two of these bath-tubs, however, are disconnected from the water-supply. In this district and in the regions immediately surrounding it there are no public baths.

When such conditions come to light a picture of probable concomitant conditions immediately flashes upon the mind of the physician whose practice has made him familiar with such neighborhoods. In this particular case, we reflect that about one-third of the clothing manufactured in Chicago is made in the "sweat-shops" in this neighborhood. We remember that a great part of the "scab cigars" (*i.e.*, those not made in union shops) are made in these dirty tenements by the unwashed inhabitants. Here live a great proportion of the rag-pickers of the city, and here they house their merchandise. In one of these tenements, a year ago last winter, in a room twelve by eighteen feet, a family of six worked, cooked, and slept while they finished a lot of knee-pants. The whole family worked almost day and night for four days in order to finish a job and get money to pay for the burial of a child that had lain all of that time on a pile of stock in one corner, dead of scarlet-fever. In one of these tenements, where sixty-two women and children live on three floors, forty-nine men sleep in a basement twenty-five by ninety feet. This cellar has three windows, two in one end and one in the other, only two of which can be opened.

It is difficult for the physician to do what may seem to him his duty in the light of such conditions as these, to be found in all of our large cities. He may be indifferent to, wilfully ignorant, or negligent of these hotbeds of physical and mental disease and distress. He may take these woes to heart, and work in a small way to stop the overflowing tide of misery and suffering that he sees damming up against the future. He may, besides, inquire into the etiology, the course, and the treatment of the social and the economic malady of which these sad conditions are symptoms. He may look into the diseases of other communities and other times, and consider the result of effort to relieve, tried elsewhere. The young, philanthropic physician, the prophet who has studied medicine for love of man, cannot find a richer field for work and study than the slums of our great cities. Asia is not so inexhaustible, Africa is not so dark, and Oceanica is not so monotonous as these deserts of human life, hope, and health. The way for knowledge and good seems to be opened in the "University Settlements," in quiet, unostentatious life, work, and study among these unfortunate and hopeless people. The efforts that have been made in this direction have been made almost entirely without the aid of physicians. In the few settlements in this country there is no physician. No other resident, we believe, could so easily earn his living while at work, yet the prophet has not appeared. When he does come he will be an officer of the department of Health; he will attend the dependent and needy poor; he will help to secure the enforcement of the tenement-house laws and the factory laws; he will instruct the poor in the care of the house, and the choice of food, and in the care of the body; he will help the sick, and by means of coöperative organizations, provide for women in approaching confinement; he will study and record

the conditions and tendencies he finds in his daily occupation, and report them through proper channels; he will try to bring the knowledge of the condition of tenants to the minds of landlords and landladies, and secure some betterment of properties; and, when other means fail, he will aim to secure laws to compel humane treatment of man by man.

THE MEDICAL CORPS OF THE UNITED STATES ARMY.

IN the overcrowded condition of the profession, together with the resultant limitation of opportunity in private practice, the recent graduate in medicine will find much to attract him to the Medical Corps of the United States Army. The standard of requirements is of course elevated, and the appointment is, therefore, the more highly to be prized. Recent innovations, to which allusion has already been made (THE NEWS, July 8, 1893, p. 51), have, besides, greatly elevated the desirability of the positions in the Corps.

In the organization of the Army Medical School four professors will be selected from among the senior medical officers of the army stationed in or near the city of Washington, and as many associate professors as may be required to give practical laboratory instruction in the methods of sanitary analyses, microscopic technic, clinical microscopy, bacteriology, urine analysis, etc.

The faculty of the Army Medical School will consist of:

1. A *President of the Faculty*, who shall be responsible for the discipline of the school, and who will deliver a course of lectures upon the duties of medical officers in war and peace (including property responsibility, examination of recruits, certificates of disability, reports, rights, and privileges, customs of service, etc.).

2. A *Professor of Military Surgery* (including the care and transportation of wounded).

3. A *Professor of Military Hygiene* (including practical instruction in the examination of air, water, food, and clothing from a sanitary point of view).

4. A *Professor of Clinical and Sanitary Microscopy* (including bacteriology and urinology).

The position in the Medical Corps is a most honorable one. The pay and emoluments are quite reasonable, while original investigation and study relating to scientific medicine or hygiene will receive due encouragement.

There are at present five vacancies in the Corps, and five more will occur within a year. To save unnecessary expense to candidates, those who desire it may have a preliminary physical examination and a mental examination in the "elementary branches of a common school education" by a medical officer of the army stationed most conveniently for this purpose. This will enable those who would be rejected on account of physical defects, or whose preliminary education is unsatisfactory, to ascertain the fact without going to the expense of visiting a distant city for the examination, and will save them the humiliation of being known at home as rejected candidates. It will also diminish the number of rejections by the board. There has been a mistaken idea, due to the large number of rejections, that the examination is unreasonably severe; as a matter of fact this is not the case, and the considerable number of rejections has been due to the fact that a large number of applicants have been men whose English education was defective and who have appeared before the board without having made any special preparation for the examination in professional branches.

A BUREAU OF PUBLIC HEALTH.

UNITED effort on the part of the medical profession seems likely to lead to the establishment of a Bureau of Public Health, of the necessity of which the recent cholera-scare must surely have furnished sufficient demonstration. It is not alone, however, for imported disease that some central form of health-organization is absolutely necessary, but also to secure uniformity and harmony, and thus greater efficiency, of action with regard to measures for the prophylaxis and management of disease within our borders. The American Medical Association has created a committee which is charged with the duty of promoting the establishment of a Bureau of Health, and now a sub-committee of the National Quarantine Committee of the New York Academy of Medicine has been instructed to prepare a bill, to be submitted to Congress, creating a Public Health Organization in the General Government. With a view of harmonizing conflicting opinions as to the plan of organization, and in order to concentrate upon a single measure the efforts of all interested in securing the necessary legislation, the committee has

prepared the sections of a bill organizing a Bureau of Public Health, which is tentatively submitted for the purpose of eliciting a full and free discussion of the subject before the precise form to be adopted is finally decided upon. The bill provides for the grouping of the States and Territories into nine sanitary districts, and the establishment of a commission of fifteen, of whom eleven are to be appointed by the President, one from each district, and two at large, the other four members to be the Surgeon-General of the Army, the Surgeon-General of the Navy, the Supervising Surgeon-General of the Marine-Hospital Service, and an officer, learned in the law, detailed by the Attorney-General from the Department of Justice. Argument seems superfluous. A Bureau of Public Health is indispensable to the welfare of the country. This once admitted, the details of organization and execution will demand separate consideration.

EDITORIAL COMMENTS.

Albuminuria as a Result of the Act of Parturition.—Modern obstetrics has done much to clear up the pathology of the gravid, parturient, and puerperal conditions. Perhaps the greatest amount of discussion has centered about the condition that for want of a better name is called eclampsia. A knowledge of the etiology of this condition would practically mean also a recognition of the means of its prevention and treatment. Many clinicians admit that there may be a physiologic albuminuria, as, for instance, after the taking of albuminous food and after active physical exercise. Recent observations by AUFRECHT and FRIEDEBERG (*Centralblatt für klinische Medicin*, 1893, No. 22, p. 457) demonstrate that transient albuminuria may occur in women as a result of the act of parturition. The observations were made upon healthy puerpera, free from gonorrheal infection, and were conducted as follows: The urine was examined in the usual manner before the onset of labor. In case the woman was in labor at the time of entrance into the hospital and was unable to spontaneously evacuate the bladder, the urine was withdrawn by means of the catheter, the most scrupulous aseptic precautions being observed. The urine was withdrawn by catheter at the conclusion of labor and again examined. In cases in which the urine presented any abnormality the examination was repeated twenty-four hours after the conclusion of labor. Thirty-two puerperal women were examined in the manner outlined. In none did the urine contain albumin before the occurrence of labor. In eighteen, however, albumin was found after labor in varying proportion; in none were tube-casts found, and in but one a small number of red-blood corpuscles. It thus seems reasonable to infer that the albuminuria is a result of the activity of labor, perhaps through venous stasis from the pressure upon the abdominal viscera and forced expiration with closed glottis. The practical lesson to be learned is that the urine should be faithfully and repeatedly examined immediately before labor, and, if albumin be present, that untoward symptoms should be carefully looked for, on the appearance of which the labor should be terminated as quickly as possible. This injunction applies with special emphasis if eclampsia (which is almost invariably associated with albuminuria) has appeared. If artificial labor is not practicable chloral hydrate is perhaps the next most useful agent.

Shamelessness Extraordinary.—From a widely-scattered circular, appealing to the morbid fears of the sexual hypochondriac in the customary language, we quote:

"In all cases where the organ is small, or where it has become relaxed through self-abuse, disease, or age, the conjestor, developing liniment, and nerve seeds should all be used at the same time.

The price of the conjestor is	$10 00
Three bottles of developing liniment . .	5 00
Six packages of nerve seeds	5 00
One suspensory bandage	2 00
	$22 00

"When the whole course of treatment is ordered at one time, we will prepare and send by express to any address on receipt of $20.00."

It is fully explained in other parts of the circular that the "conjestor" acts like a cupping glass, the air being exhausted, etc. The drug stores are acting as local agents in this execrable traffic. Is there no city law or State law in Chicago to stop it?

The Value of the Hands and of the Fingers.—Surgeons have often to estimate the chances of saving injured hands, and the comparative values of hands and fingers. According to a scale of value furnished by the Miners' Unions and Miners' Accident Insurance Companies of Germany, the loss of both hands is valued at 100 per cent., or the whole ability to earn a living. Losing the right hand depreciates the value of the individual as a worker 70 to 80 per cent., while the loss of the left hand represents from 60 to 70 per cent. of the earnings of both hands. The thumb is reckoned to be worth from 20 to 30 per cent. of the earnings. The first finger of the right hand is valued at from 14 to 18 per cent., that of the left hand at from 8 to 13.5 per cent. The middle finger is worth from 10 to 16 per cent. The third finger stands least of all in value; although, like other useless members of the community, it is surrounded by riches, its value is only from 7 to 9 per cent. The little finger is worth from 9 to 12 per cent. The difference in the percentages is occasioned by the difference in the trade, the first finger being, for instance, more valuable to a writer than to a digger.

Abolish the Cellar.—In a recent number of *The American Architect*, Mr. Edward Atkinson deals with the financial and architectural aspects of the question, *Cellar or No Cellar?* and easily shows that *no cellar* is by all odds preferable. The article proceeds upon the assumption that the influence of the cellar on health is pernicious—a truth that will hardly be doubted by hygienists. Almost every observant physician in general practice has met with cases of obstinate malaria and

various forms of ill-health that were probably or certainly due to the gases arising from the dank, undrained, unlighted hole beneath the house called a cellar. Of what possible use can such a hole be to a family if a house were rightly constructed is beyond human ingenuity to discover. In addition to its inevitable condition and quality, it is often also made the dumping-place of ashes, refuse, and all sorts of household débris. Now that it is proved not to be necessary, either from financial or architectural reasons, let the noisome nuisance be abolished!

Supernumerary Breasts and Multiple Pregnancy.—At a recent meeting of the Paris Société Médicale des Hôpitaux, MARIE (*La Semaine Médicale*, No. 38, p. 303) showed the photograph of a young woman who presented a supplementary nipple of the left breast. This anomaly had been the rule in the family of the woman through at least four generations. It was also an interesting fact that of eleven brothers and sisters four were twins, and that of fifteen brothers and sisters of the woman's father six were twins, and these alone presented the supernumerary nipple. This observation would seem to indicate that there is a correlation between the existence of supernumerary breasts and multiple pregnancy, and that the condition is not a simple erratic malformation, but an atavistic reversion to an ancestral type. That the faculty of multiple procreation does not reside alone in the female is demonstrated by the fact that the father of the patient begot two pairs of twins, and that one of his brothers (also a twin) begot at least one pair of twins.

Yellow Fever in Georgia.—From the *Abstract of Sanitary Reports* we learn that the captain of a sailing bark died June 25th, of yellow fever, on the Satilla River, near Brunswick, Ga. The local health officer was authorized by the Surgeon-General of the Marine-hospital Service to transfer twenty-five laborers who had been loading the vessel to Sapelo Quarantine for detention and observation. It appeared that the vessel had entered Havana on May 19th, and had unloaded in the open bay, no one going ashore but the captain. She sailed from Havana on June 9th and reached Satilla on the 15th. All hands had been well at Havana, during the voyage, and upon arrival. The vessel was discharged from quarantine June 19th, after being fumigated, and was towed to Satilla on the same day. The master was taken sick on June 21st, and a day later transferred to a camp eight miles in the country on the Satilla.

Responsibility for Negligence.—If a physician by the slightest negligence permits the death of a single patient he is held responsible for the death by the law and is punished accordingly.

And justly so!

If a public officer by the grossest neglect causes the deaths of many people (as in the disasters of Ford's Theater, the Coney Island Railroad accident, the holocaust at the World's Fair, etc.), nobody seems to be to blame, leastwise nobody is punished.

Is justice a matter of party and profession?

Long-lived People.—An English investigator has examined the habits of centenarians. They were almost invariably lean people, of spare habit, and of great moderation in eating and drinking. Of thirty-seven, three took no animal food, four took very little, twenty a little, ten a moderate amount, and only one acknowledged taking much meat. With regard to alcohol, the returns are much the same, and abstemiousness is found to be the rule of life with these centenarians. Fifteen had been total abstainers, either during the whole or part of their lives; two took very little alcohol, twenty-two a little, and ten a moderate amount.

Bacteria in the Soil at Different Depths.—Some investigations carried out by Dr. Alexander A. Houston, of Edinburgh, respecting the number of bacteria in the soil at different depths from the surface, go to prove that the microörganisms become less and less abundant as the depth from the surface increases. For example, the average number of germs in a gram of soil examined, which was taken from the surface, was 1,687,799; at a depth of three feet this average fell to 173,807; and at a depth of six feet it was only 410. These figures are interesting, and would tend to show that at certain definite distances from the surface the soil would be sterile.

Wild Animals and Snakes in India.—From a recent number of the *British Medical Journal* we learn that in 1891 24,300 persons were destroyed by wild animals and snakes in India, as against 23,801 in 1890. By far the larger proportion of deaths was due to snakes—more than 21,000 in each case. Cattle also suffered largely, but wild beasts are more fatal to them than snakes. The number of deaths relatively to population was from wild beasts 1 in 74,597 and in snakes 1 in 10,166.

A Valuable Constituent of the Human Body.—A chemist computes that at the present market value, the average human cadaver contains something like eighteen thousand dollars worth of calcium. But, like the fabulous values of aluminum in clay, or of the gold in seawater, the cost of extraction at present prevents all profit to the would-be enterprising manufacturers, and the schools of anatomy will have no immediate cause for alarm as regards commercial competition.

Physiologic Examinations of School-Children of Washington are being made in order to determine the comparative rates of growth, influence of nationality, school hygiene, density of population, systems of physical culture, etc. Special measurements of the nervous system with the esthesiometer, dynamometer, baresthesiometer, and thermesthesiometer, are being made by Dr. MacDonald, to estimate the proper amount of study required, the proper age of advancement, etc.

A Husband's Consent not Necessary to an Operation on His Wife.—In a recent English case, in which a woman consented to have an operation performed, the husband's refusal did not reach the surgeon until the death of the wife, from chloroform. It was decided that in such instances the husband's consent was not legally necessary. But if not legally a prerequisite, should it not have been ethically required—provided, of course, the case was not one of great urgency?

An Aluminum Drainage-tube.—The use of aluminum in the arts is constantly extending. The advantages of the metal are essentially its lightness, its cheapness, its freedom from corrosion, and its pliability. One of the latest purposes to which it has been adapted is the making of drainage-tubes, the credit of which belongs to Dr. F. B. Robinson, of Chicago.

REVIEWS.

MANUAL OF CHEMISTRY. A GUIDE TO LECTURES AND LABORATORY WORK FOR BEGINNERS IN CHEMISTRY. A TEXT-BOOK, SPECIALLY ADAPTED FOR STUDENTS OF PHARMACY AND MEDICINE. By W. SIMON, Ph.D., M.D., Professor of Chemistry and Toxicology in the College of Physicians and Surgeons, Baltimore, and Professor of Chemistry in the Maryland College of Pharmacy. New (fourth) edition. 8vo, pp. 490. Philadelphia: Lea Brothers & Co., 1893.

THE appearance within a year of another (the fourth) edition of Professor Simon's work indicates that our favorable opinion of the book, as already expressed, is shared both by teachers and students. The new and unique feature of representing color-reactions and colored precipitates by artistically produced illustrations is attractive, and cannot fail to become part of an object-lesson, so necessary for the successful study of chemistry.

The author has only in part accepted the uniform system of orthography and nomenclature for chemical terms recommended by the American Association for the Advancement of Science. In text-books such changes, however much they are to be desired, will be gradual.

The fifth part of the work, devoted to analytic processes, deserves favorable mention, and though the methods might have been entered upon more fully, this is hardly to be expected in a book of such compass as this.

The classification of the hydro-carbon derivatives is not in keeping with the usual custom of teaching them according to their production, first, by halogen substitution, and subsequently increased oxidation. This will, probably, make their study more difficult, as the student will lose sight of the systematic manner in which they are connected, and will have to impress them on his mind as isolated facts.

The consideration of the ptomaïnes, leukomaïnes, and toxalbumins, as well as the different albuminoids, together with the animal ferments, is an evidence that the author has kept his work up to modern advances.

The most important improvement and changes are found in Part VII, on Physiological Chemistry, which is of interest to the physician and student. The food-metamorphoses and the animal fluids and tissues are well treated; the introduction of the chemical study of the gastric juice is to be commended, though researches in this direction have been so great that it is hardly to be expected that a book like this should do full justice to the subject. The chemistry of the milk, as well as that of the urine, has been much enlarged, and, though some features might to advantage be introduced in the analysis of the urine, such as polarimetry and Haycraft's method for the determination of uric acid, the improvement in this direction has been very marked.

By frequent editions of this work Professor Simon has been enabled to perfect it so that it can be said to rank with the best text-books on pharmaceutic and medical chemistry in this country.

DISEASE IN CHILDREN. A MANUAL FOR STUDENTS AND PRACTITIONERS. By JAMES CARMICHAEL, M.D., F.R.C.P., Ed., Physician to the Royal Hospital for Sick Children; University Lecturer on Disease in Children, Edinburgh. 8vo, pp. xvi, 591. New York: D. Appleton & Co., 1892.

ATTENTION is at once attracted by the title of this work, "Disease *in* Children," in contradistinction to the diseases of children. In the text it is aptly pointed out that "It is not strictly correct to talk of diseases *of* children, as we would of women, who suffer from ailments peculiarly their own." The subject is considered in forty-five chapters and an appendix. A strange distinction is made by which typhoid fever, typhus fever, measles, Rötheln, diphtheria, varicella variola, vaccinia, erysipelas, epidemic cerebro-spinal meningitis, pertussis, and croupous pneumonia are considered as "fevers" and tuberculosis and syphilis as "infective diseases." There are numerous other evidences of the struggle to break away from early precept and the traditions of a previous generation. Thus, it is recorded that "diphtheria is essentially a miasmatic" disease; eleven pages are devoted to a discussion of scrofulosis, which is considered as an indication of "a disposition or tendency to certain definite pathological evolutions, a diathesis in which, under varying conditions, certain tissues become affected with diseased [disease-] processes of a peculiar type, constituting the scrofulous cachexia"; "tuberculosis of the lung" is said to be "usually a local expression of general tuberculosis," and is discussed under the subdivisions "acute phthisis," "chronic phthisis," and "caseous broncho-pneumonia or catarrhal phthisis." On the other hand, we find a general and almost unreserved acquiesence in the germ-etiology of the diseases commonly accepted as infectious; and in the same tendency true croup and laryngeal diphtheria are considered synonymous terms. An excellent and comprehensive scheme of clinical examination is given which we can heartily commend, for we are among those who believe that examinations and records can never be too fully or too carefully made. We are convinced that more mistakes in diagnosis result from carelessness of investigation than from ignorance. Under the treatment of scarlatina it is stated that "three methods deserve notice: isolation, disinfection, and inoculation. The last method has not yet been accepted by the profession, but it is certainly warranted in principle, if a modified or attenuated virus could be obtained, which, by inoculation, would confer immunity from the disease. Experiments in this direction have already been made by Dr. Strickler, in America, who inoculated children with virus obtained from the horse supposed to be suffering from scarlatina or an allied disease. The children contracted local sores at the point of puncture, and some degree of lymphatic enlargement in the neighborhood, and subsequent immunity from the disease after exposure to infec-

tion." We have in the foregoing noted most of the points by which we were especially struck in a reading of the work; there is, however, a good deal to commend. The various sections are well written, and bear the stamp of large experience and careful observation.

A TREATISE ON RUPTURES. By JONATHAN F. C. H. MACREADY, F.R.C.S., etc. With twenty-four lithographed plates and illustrations in the text. 8vo, pp. 442. Philadelphia: P. Blakiston, Son & Co., 1893.

As surgeon to the City of London Truss Society, Mr. Macready has enjoyed special opportunities for the study of hernia in its various forms, as well as of the methods of its treatment and their results. In the present work he not only gives the teachings of his own experience, but has drawn on his very extensive acquaintance with the literature of the subject, ancient as well as modern. With these resources he has prepared a most valuable treatise, so clearly written that a tyro may read it, and yet so comprehensive that a practitioner of long standing may find instruction in it.

The author expresses his preference for the term "rupture," as indicated in the title given. We must confess that his reasons for this seem to us insufficient. The word "hernia" has, indeed, been sometimes misapplied; but, as he admits, the word rupture conveys an incorrect idea of the pathology of the affection, and is perfectly proper when employed to designate, for example, the tearing of a muscle or a vein.

The arrangement of the subject seems to us very philosophic. Part I, embracing thirty-three chapters, deals with conditions not involving disturbances of the function of the bowel. Part II contains seven chapters, and is devoted to those in which that function is interfered with. Of course, the two are not absolutely distinct, but they are sufficiently so for the practical purpose of discussion.

Another good feature of this book is the placing at the end of each chapter of the references contained therein, they being indicated in the text by numbers in small type.

The various forms of hernia are well and clearly described. As to the theories of the production of such lesions, the long mesentery theory, the dragging theory, and the theory of pressure from within, we agree with our author in favoring the last-named.

An interesting exposition is given of a matter that too often escapes the notice of surgeons—the changes of shape that the abdomen undergoes in cases of long-standing hernia, especially in persons in advanced life.

So far as can be judged from the illustrations and descriptions in this work, we should judge that the trusses in use in England are much more complex and clumsy than those generally employed in this country. And we think our author has laid too little stress upon the importance of accurate fitting of the whole apparatus. It is not the amount of force, but the exact application of it just where it is needed, that makes a truss efficient.

As to the radical cure of hernia by operation, the different methods are clearly though briefly described; and while no one procedure is specially advocated, preference seems to be given rather to those by open wound than to those that are done subcutaneously.

The illustrations are excellent. The book is well and accurately printed, and will doubtless be accorded the favor that it fully deserves.

HANDBOOK OF INSANITY FOR PRACTITIONERS AND STUDENTS. By DR. THEODOR KIRCHHOFF, Physician to the Schleswig Insane Asylum, and Privatdocent at the Kiel University. Illustrated with eleven plates. Pp. 362. New York: William Wood & Co., 1893.

THIS volume, which is one of the "Medical Practitioner's Library" series, is without a preface. It is made up of two parts called general and special parts. The former, comprising 178 pages, treats of the anatomic basis and the location of mental disturbances, and the classification, causes, symptoms, diagnosis, treatment, and history of insanity. The latter part deals with the various special forms of insanity, which are divided into "Simple mental disorders," and "Mental disorders associated with permanent anatomical changes in the brain or with general diseases."

The general part, which is very readable, discusses the whole subject of insanity from a broad and comprehensive standpoint, and would be exceedingly helpful, we believe, to the student or general practitioner attempting to grasp the subject of insanity. It serves as an excellent introduction to the special part.

While a conservative spirit is maintained throughout the work, making it a safe guide, yet the author shows familiarity with the investigations and progress of recent years. His views on mechanical restraint are most sensible. He says: "In rare cases, however, it would be fanatical to dispense with restraint." In places the conservatism is extreme: for example, when he says that all remedies other than the bromids are useless in epilepsy. A number of excellent plates representing typical forms of insanity will be helpful to the student. The publishers' work is very creditable.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-fourth Annual Meeting, held at Milwaukee, Wis., June 6, 7, 8, and 9, 1893.

(Continued from page 84.)

SECTION ON DERMATOLOGY AND SYPHILOGRAPHY.

FIRST DAY—JUNE 6TH.

DR. L. A. DUHRING, of Philadelphia, read the President's Address, which was entitled "The Scope of Dermatology." He pointed out the difficulty of separating so-called cutaneous diseases from many general diseases accompanied by cutaneous symptoms.

The term "skin-diseases" can no longer be used in its ancient sense, and these affections cannot be looked upon as morbid entities, as diseases whole and complete in themselves. The tendency of modern dermatology is to use the term to include all of the morbid manifestations that may occur upon the integument.

The objective study of affections of the skin is fascinat-

ing and very important, but it is not comprehensive enough, without invoking the aid of general pathology and considering the relations of the skin to the general economy. Cutaneous diseases must be studied not only as localized areas of superficial disease, but as indexes to disease elsewhere, or as a key to some morbid process that may originate or have its seat in other tissues of the body. The strictly local nature of some diseases is plain, as in the parasitic affections, certain inflammations due to local causes, as rhus poison; but while this holds true for a considerable number of diseases, there are still many that are in reality widespread diseases, the integument being only one of the organs of the body involved in the process, as the so-called exanthemata, other eruptive fevers, the eruptions due to various poisoned states of the system, as in septicemia, glanders, leprosy, and syphilis. Our ideas of the so-called skin-diseases, and the whole subject of dermatology, must be greatly enlarged. This branch of medicine should include all morbid manifestations that appear on the skin, whatever may be their cause, nature, and character. Dermatology has properly to do with the integument and all that pertains to it, and, moreover, with all of the varied causes that may disturb this organ.

The idea of the vast array of cutaneous affections being morbid entities confined to the skin must, in many cases, be abandoned in favor of the principles of general medicine. We should study these diseases with the view of learning all that they can teach us, not only of the skin, but of general pathology. We should look in the majority of cases beyond the mere eruption, valuable and important as this is in all cases as a guide to the pathologic process at work. The cutaneous disturbance in many instances is distinctly indicative of some disorder, irritation, or localized disease in other regions, organs, structures, or fluids of the body.

Dermatology should be for the physician as a key with which the skin is made to reveal, in many instances at least, the nature of the morbid process in the general economy, or in other organs, which without this aid might remain obscure, as in the exanthemata, syphilis, leprosy, and other diseases.

Dr. Ohmann-Dumesnil, of St. Louis, read a paper entitled "Erythema Exfoliativum Recurrens." He referred to six cases of this interesting affection, giving the reasons why the term erythema is used, instead of dermatitis. He believes erythema to be dependent upon an exaggerated circulation, while dermatitis is a true inflammatory process.

In the cases reported there was an infiltration of lymph-cells, with a periodicity of the attacks, such as occurs in hay-fever. The mental condition may have some influence in the production of these attacks.

Dr. Grindon, of St. Louis, pointed out that an erythema often degenerates into a dermatitis. In the cases reported the cutaneous manifestations may have been due to the presence of some irritant in the blood, such as toxalbumins or bacteria.

Dr. Lydston, of Chicago, likewise believed the trouble to be due to a condition of toxemia. The recurrence of the disease is comparable to the recurrence of attacks of epilepsy and of other neuroses.

Dr. Ravogli, of Cincinnati, referred to a case of ichthyosis, in which a layer of epiderm as hard as wood formed upon the fingers, after a time being thrown off like the stalls of a glove, the fingers remaining entirely well until, following the occurrence of neuralgic pains, a new layer would form, to be disposed of in the same way as the former one.

This case, and those reported, were considered as tropho-neuroses, in the mechanism of which the vaso-motor nerves play an important rôle. The erythemata nearly all display a tendency to relapse. It is often difficult to state when an erythema becomes a dermatitis. When, however, exudation and necrosis of the horny layer occur, the process is more profound than a simple hyperemia.

Dr. A. Ravogli, of Cincinnati, read a paper "On the Nature of Eczema," detailing the results of some unfinished experiments. The inoculation of rabbits upon the shaved ear with pure cultures of the staphylococcus pyogenes albus yielded no result. After blistering both ears of rabbits by means of croton oil, one ear was inoculated with the cultures. The uninoculated ear returned to its normal condition in six or seven days, while the other, after a week, began to inflame and to discharge a serous fluid, and subsequently became covered with thick, yellowish crusts, on removal of which excoriations appeared. The symptoms were quite like those of eczema, and continued for more than four weeks.

The conclusion was reached that eczema is not simply a dermatitis, but that dermatitis is the cause of eczema, which is a chronic process, in most cases dependent upon the presence of the staphylococcus beneath the epithelial cells.

Dr. Bulkley objected that all cases of eczema are not chronic in course. The condition may also be acute. In many cases the cause is to be found in the nervous system.

Dr. Duhring admitted the distinction between eczema and dermatitis. Clinically, some cases conform to the type of eczema, while others are instances of ordinary dermatitis. There are still other cases, however, in which the clinical picture is complete. Great difficulty attends an etiologic classification of eczema.

Dr. Ravogli stated that a knowledge of the etiology of disease must lead to the application of remedies with greater certainty of success. He had no doubt that purulent discharges frequently form the starting-point of eczema, and that the affection is thus often contagious. A healthy epidermis constitutes a safeguard against the action of the staphylococci, but when the epidermis is scratched or inflamed the conditions are favorable for the production of eczema. The experiments thus far made have been limited to the staphylococcus albus, but the staphylococcus aureus and citreus will be similarly studied.

Second Day—June 7th.

Dr. L. D. Bulkley, of New York, read a paper entitled "Notes on Feigned Eruptions." He related the case of a girl who had been ill with spinal meningitis, and who presented some twelve red patches of excoriation upon the cheeks, covered by crusts; other patches were scattered on the temples, others on the neck. On the arms were abrasions of the skin, running in the axis of the limbs, with inflammation more severe than on the face. The affection was painful, but its nature was doubtful. The girl was intelligent, but presented a

neurotic history. Careful study of the lesions aroused the suspicion that they were self-produced. The object was found in the desire to go to a certain watering-place. It was learned that the lesions had been produced by rubbing the skin with sand paper.

In another case, in a child of wealthy parents, superficial excoriations were present upon the feet, leg, arm, with some erythematous areas upon the face. Many remedies had been used without avail, until it was found that the eruption was caused by rubbing the skin with the fingers, from which a pleasurable sensation was derived. The sexual sense is sometimes stimulated by rubbing certain portions of the skin.

DR. OHMANN-DUMESNIL referred to the case of a woman who produced sores on her chest by applications of argentic nitrate.

DR. FRANK referred to the case of a boy who, having learned that the taking of antipyrin would be followed by the appearance of an erythematous eruption, would take the drug for the purpose of producing the eruption, in order to be kept from school.

DR. GRINDON said that he has seen children that had cut off the eyebrows and eyelashes to simulate alopecia. He referred to the case of a man of remarkable intelligence who used to burn his arm with a lighted cigar.

DR. LONGFELLOW, of Cincinnati, referred to the case of a dressmaker, who had an acne eruption, and took large doses of potassium iodid for the purpose of maintaining the eruption.

DR. RAVOGLI related the case of a young man who, to escape military service, produced an eruption of large blisters and excoriations by the application of the cortex of timelia. He referred to the practice, in certain parts of Italy, of inoculating tinea favosa from one person to another for the purpose of securing exemption from military duty.

DR. DUHRING stated that he has seen very few cases of feigned eruptions, and most of these in dispensary practice, and not in private. He has also seen eruptions that might have been taken for feigned eruptions, but which were really produced by nature. In the case of one woman, who presented symptoms of hysteria, and had puzzled many physicians, an eruption that was supposed to be artificial, and that resembled pemphigus, was found to be a true neurotic affection of the skin.

Weir Mitchell has also reported the case of a woman who presented a large sore covered with a singular crust, which had been judged to be produced by chemicals, but it was afterward learned that it resulted from other causes.

DR. LONGFELLOW, of Cincinnati, read a paper entitled "The Local Treatment of Psoriasis." For the removal of the scales he recommended a kind of soap containing sulfur and green soap. As an application to the skin, he recommended a mixture of collodion and tar, and also chrysarobin and pyrogallic acid mixed with collodion.

DR. OHMANN-DUMESNIL said that psoriasis of the scalp, especially in women, will not usually submit to the means recommended. He therefore uses oil of cajuput, which he finds very useful and of easy application.

DR. BULKLEY recommended the use, twice a day, of an ointment containing hydrarg. ammoniat., bismuth. subcarb., āā ℥ss; acid. carbolici, gtt x; unguentum ammon. rosat., ℥ij—M. Ft. unguent. The scalp should not be washed too often. Aristol is useful, as is pyrogallic acid, 5 per cent. in collodion, covered with wax paper. Twenty-five per cent. of the cases can be better cured by means of internal and hygienic means than by means of local treatment.

DR. GRINDON read a paper entitled "Recurrent Zoster." He called attention to varieties of vesicular eruption that display a tendency to frequent relapse, but which also resemble zoster, though failing to show all of its characteristics. These varieties he designates zosteroids.

DR. RAVOGLI read a paper entitled "Purpura Recurrens." He referred to two cases, one in a male the other in a female, both of whom presented petechiæ on both legs, with edema and pains in the joints, relapsing every two or three weeks for a long time. There was no fever. No albumin could be detected in the urine, but there was marked anemia, the diminution in the number of red corpuscles being the principal feature. Both cases had been treated with anti-rheumatic remedies without benefit. Under treatment with tincture of ferric chlorid and nux vomica internally, and the application of rubber bandages to the extremities, complete recovery ensued.

The hemorrhagic extravasations were ascribed to diminished plasticity of the blood itself from a deficiency of albumin and the badly nourished condition of the tunics of the bloodvessels.

The edema is to be explained by the diminished resistance of the tissues and the increased intra-vascular pressure, with lymph-stasis. The recurrence is related to the functions of the vasomotor nerves. Anemic individuals are more susceptible to stimuli than others.

DR. FRANK read a paper on the "Treatment of Ulcers of the Leg." He classified ulcers as idiopathic and symptomatic, and referred them to (1) want of circulation, and (2) stasis. The condition occurs most frequently among the poor, who are obliged to engage in hard work.

In treatment, zinc-gelatin was recommended to keep the ulcer from contact with the air, and speedily leading to recovery.

DR. RAVOGLI related that he had found it wise to omit the use of zinc-gelatin in cases of fluid discharge. Some cases are attended with such intense pain that the patient cannot bear the presence of an impermeable dressing. In these cases the application of cold water, in the form of a bath, will diminish the inflammatory symptoms. When the necrotic tissue undergoes sloughing, antiseptics are indicated, followed by the application of adhesive plasters, so as to bring as intimately in contact as possible the edges of the ulcer. When the ulcer has callous edges, which retard recovery, these should be cut off with scissors. At the conclusion of the treatment, when the leg is infiltrated and shows varicose veins, the application of the rubber bandage is essential.

DR. PRICE expressed the view that in most cases a saturated boric dressing is the most appropriate, while in some applications of a watery solution of tannin are the most satisfactory. In callous ulcers scarification through the scar-tissue, and an antiseptic dressing are often successful. Balsam of Peru has good effect in stimulating the granulations; as does also the application of a sheet of lead to the ulcer.

DR. M. B. RICKETTS presented a paper entitled "The Obliteration of Pigmentation on the Human Skin, with Experiments."

DR. BULKLEY read a paper "On the Use of Waxed Paper in Dermatologic Practice." He said that twenty years ago attention was called to the use of waxed paper in certain diseases of the skin. This is not intended to take the place of collodion, but only to be employed when it is desired to exclude the air from the affected surface.

DR. DUHRING announced a formula for tincture of coal-tar, which he has found useful in many affections of the skin, and which may be combined with other substances in the form of an emulsion. Aqua bituminis, tinctura picis, coal-tar dissolved in alcohol, caustic soda, and tincture of elm make a fine mixture.

DR. DUNN presented a paper entitled "A Case of Leprosy in a Native American without Known Infection."

CORRESPONDENCE.

ENLARGED AND DISPLACED SPLEEN.

To the Editor of THE MEDICAL NEWS,

SIR: Your excerpt from the *Annals of Surgery* on the "Operative Removal of an Enlarged and Displaced Spleen," published in THE MEDICAL NEWS of July 8, 1893, induces me to mention a case that came into my hands in 1889, to illustrate our liability to err in the diagnosis of enlargements within the body, and to record the peculiar termination of the case.

In the fall of 1888, while attending a member of the family of M. T., a farmer living in the Missouri River bottom in Clay County, Missouri, a malarious locality, my attention was called to an enlargement in the *right* inguinal region of Mrs. M. T., a woman thirty-two years of age, who had borne five healthy children. The enlargement was at the time apparently about the size of a child's head at birth, rounded, and more or less firm, but not hard. It was not freely movable, though it could be moved somewhat.

Mrs. M. T. was in fairly good health, of spare build, and light complexion. The tumor had existed for about six years, varying in size, being sometimes larger and sometimes smaller. The woman had never suffered much pain. Neither her appearance nor her history indicated chronic malarial infection. I advised her to let the mass alone until such time as it became troublesome and gave her distress, when an operation would be demanded.

I was called to see her again in the spring of 1889. The time for operation had apparently arrived, as in the previous few weeks the tumor had enlarged considerably and had become quite painful. I called upon a prominent surgeon to examine the case with me, and an operation for the removal of the mass was decided upon. While on the table, under ether, a closer examination noted the absence of the spleen from its proper place. A hypodermatic syringe, armed with a long needle, revealed the contents of the tumor to be blood, and the operation was postponed indefinitely. The woman was at that time four months pregnant. She was put upon the old-fashioned tincture of iron, iodin, Fowler's solution, and glycerin mixture, and the enlargement duly decreased and almost disappeared.

In September she was delivered of a healthy child. Nothing noteworthy occurred during the labor or puerperium. Six weeks thereafter, however, I was called in haste on Sunday morning to see the patient, as the tumor had rapidly enlarged and was very painful. I found it occupying its place in the *right* inguinal region. It was about the size of the average adult's head. My efforts to allay the pain were only partially successful. The temperature was normal. There was thirst, which increased up to the time of her death on Monday at noon. The bowels were moved three or four times naturally during Sunday and Sunday night. Vomiting was troublesome all day Sunday, and, by Monday morning, became stercoraceous. The skin assumed an ashy-white color.

I made a post-mortem examination on Tuesday morning, and found the enlargement to be the spleen. Death was caused by the accidental twisting of the elongated pedicle, which was about half the size of my wrist. The spleen had been turned completely around twice, strangulating the splenic vessels and causing rupture of the rounded portion of the organ opposite the attachment of the pedicle. There were three points of rupture: one about five inches in length and half an inch deep, and two shorter ones on either side of the long one and about an inch from it. It is needless to say that the peritoneal cavity was full of blood.

Viewing this case retrospectively, the woman's life might have been saved by replacing the spleen at the time of preparation for operation six months before, but nothing seemed to warrant such a procedure at that time. When last called, untwisting the pedicle, suturing the rents, and cleaning out the peritoneal cavity might have enable her to recover.

Respectfully, H. O. BEESON, M.D.

NOEL, MCDONALD CO., MO.

DIABETES MELLITUS IN A CHILD, WITH RECOVERY.

To the Editor of THE MEDICAL NEWS,

SIR: That a form of diabetes mellitus can exist in a child, from which perfect recovery is possible, I am led to believe from a case coming under observation in April, 1890.

E. J., aged six years, having consumed quite an amount of sugar-water, taffy, "wax," and other saccharine products of the sugar-making season of 1890, was observed by his parents to have quite an increase of frequency in micturition, coupled with great thirst, emaciation, and increasing weakness, though preserving a good appetite. This condition had lasted, to their knowledge, two or three weeks when brought to my notice. The amount of urine excreted amounted to from eight to ten pints. The secretion was of pale-straw color, had a specific gravity of 1040, and responded quickly to every sugar-test that could be made.

Reserving a prognosis in such a case, occurring in a family in every way healthy, and with no other known cause than the ingestion of excessive quantities of the product of the sugar maple, I placed the little fellow on five drops of the fluid extract of ergot every four hours,

prescribing an anti-diabetic diet, and ordered laxatives to overcome the constipation, which had been constant from the beginning.

In a week the specific gravity of the urine was down to 1028, and in two weeks it was normal. The boy made an uninterrupted recovery, and is now a healthy lad, although he at one time had saccharine urine for at least five weeks.

Respectfully,

W. W. PENNELL, M.D.

FREDERICKTOWN, O.

PRECOCIOUS PREGNANCY.

To the Editor of THE MEDICAL NEWS,

DEAR SIR: As an addition to your list of early pregnancies the following may be of interest:

G. T., a well-developed colored girl of this city, after a normal labor, gave birth, April 24, 1893, to a small, but apparently full-term female child. The mother was born, according to the statement of her parents, on June 1, 1879, and was consequently thirteen years, ten months, and twenty-three days old, when her child was born. The little one weighed almost six pounds, and at first did well, but died, after four or five weeks, from lack of proper nourishment and care.

Respectfully,

CHARLES H. PRESTON, M.D.

DAVENPORT, IOWA.

NEWS ITEMS.

New Medical College Buildings in Chicago.—The Laboratory Building for the Chicago Medical College, just completed, is a handsome and commodious structure, one hundred feet square and five stories high. The laboratories are of the most approved character and very commodious. Ample facilities are afforded for advanced laboratory work and original research. The anatomic laboratories have asphalt floors and an abundance of lockers for students' clothing and washing facilities. They are well lighted and well ventilated. An ice machine for cooling the ice-box, in which the anatomic material is kept, is one of the many novelties of construction.

Beside the Laboratory Building there is now rising another structure, which will be complete by September 1st, and is intended to furnish additional lecture-rooms for the college and model accommodations for the South Side Dispensary. The sick will be cared for, and clinical teaching will be given here both mornings and afternoons. Immediately south of these buildings is the site of Wesley Hospital. Its present temporary structure is already outgrown and will soon be replaced by a fine hospital.

Mercy Hospital, which is near by, is now being doubled in capacity, and will hereafter contain four hundred beds. This will place at the disposal of the Chicago Medical College nearly six hundred beds from which to obtain clinical instruction.

The Pan-American Medical Congress Excursion to Rome.—It has been definitely determined that the Pan-American Medical Congress Excursion to the Eleventh International Medical Congress will sail on the S. S. "Werra" from New York, September 9th, the day following the adjournment of the Congress at Washington, and will arrive at Genoa, September 20th, four days before the opening of the Rome meeting.

Round trip steamer tickets may be procurred for $142.50 for inside rooms, and $150.00 and upward for outside rooms. Tickets are good for members of the Congress and their families, and may be used at the option of holders to return on any steamer of the line from Genoa, or on Saturday steamers from Bremen, or Sunday steamers from Southampton, during the months of October, November, and December. Physicians desiring to avail themselves of this exceptionally low rate should at once become members of the Pan-American Medical Congress by sending the registration fee ($10.00) to the Treasurer, Dr. A. M. Owen, Evansville, Ind., and informing the Secretary-General, Dr. Chas. A. L. Reed, Cincinnati, of their intention to join the excursion. The trip includes a stop at the Azores and Gibraltar and a sixty hours' sail along the picturesque coasts of Spain, France, and Italy.

Dr. John B. Hamilton has assumed editorial charge of the *Journal of the American Medical Association.* Dr. J. C. Culbertson has resumed his editorial connection with the *Cincinnati Lancet-Clinic.*

A Boylston Medical Prize for 1893 has been awarded to Dr. Wm. E. Hughes and Dr. W. S. Carter, of Philadelphia, for an essay entitled, "A Clinical and Experimental Study of Uremia."

Naunyn, of Strassburg, has been elected to the chair of Internal Medicine at Vienna, as the successor of Kahler, deceased.

In Memory of J. Marion Sims.—A bronze statue of Dr. J. Marion Sims is soon to be erected in Central Park, New York.

Vidal, the eminent French dermatologist, died recently at the age of sixty-five.

DELIRIUM TREMENS.

BY GEORGE B. TWITCHELL, M.D.,
OF CINCINNATI, OHIO.

"A rigor and delirium from excessive drinking are bad."—*Aphorisms of Hippocrates.*

THE tendency at present is to underrate the importance and gravity of delirium tremens. We are warned against the old-fashioned free use of sedatives: "Feed your patient and he will get well;" "When he is exhausted, he will fall asleep anyway." Such advice is often heard. The descriptions of delirium tremens to be found in the text-books are very meager and they frequently entirely omit many of the important phenomena of the disease. Monographs describe many different forms, and are often confusing. This confusion, and indeed many of the current ideas as to the prognosis and treatment of this disease depend upon a very misleading conception, which is, that "delirium tremens is really only an incident in the history of chronic alcoholism." (Osler.) This is true, but the same might be said of cirrhosis of the liver. Delirium tremens is as much a specific disease as cirrhosis of the liver is; but the breadth of the idea that it is "only an incident" hides this important fact, and consequently many of our conceptions of this dangerous disease are founded on the observation of comparatively mild pathologic conditions. The aim of this paper is to give to delirium tremens its true importance as a disease.

The clinical observations to be used here were made during an eighteen months' service as externe and interne at the Cincinnati City Hospital. A great many cases of all grades of alcoholism are continually received at this institution, and while an effort is made to exclude simple "drunks," the policy of the receiving physician is always to err on the side of safety. So it is that many cases are received that otherwise would not be. It is extremely difficult to estimate the extent of a drunken man's illness. Alcoholism, in all its minor forms, is associated with an hysterical condition that is hard to recognize. A man is rarely so drunk as he pretends to be. When a man is suddenly sobered by some necessity, it is simply this hysterical condition that has disappeared. However, it must be remembered that nothing else so completely disguises other disease as does alcoholism. A very severe injury may be hidden under drunkenness. All the symptoms of pneumonia disappear before a concomitant delirium tremens.

During the eighteen months that I served at the City Hospital, 360 cases of alcoholism were received. Of these, 132 had delirium tremens. Many cases were under my care, or at least where I had opportunities of observing them. Others I did not see, but I obtained my knowledge of them from the clinical records. Every possible precaution was taken to insure accuracy. However, certain errors were hardly to be avoided. Probably the 360 cases of alcoholism contained more than 132 cases of delirium tremens. The cases overlooked were probably abortive cases. The inclusion of these cases (could they have been positively identified) would have reduced the death-rate given. This error is probably not very great, and is perhaps the only one that could have occurred in compiling the statistics.

ETIOLOGY.—Sometimes a man goes directly from drunkenness into delirium tremens, but more frequently the disease makes its appearance as he begins to sober up. Anstie says that the first symptom is a distaste for alcohol. I have not noticed that. The disease often begins one, two, or three days after the individual has ceased drinking. This accounts for the erroneous opinion once held that the disease was due to a withdrawal of the accustomed stimulant. No single drinking bout ever produces delirium tremens. It may cause death by alcoholic poisoning, but not by delirium tremens. It is the chronic drinker who develops this disease, and he may develop it without having ever been drunk. Usually, if not always, there is an exciting cause aside from alcoholism. Näcke lays great stress on this. By all odds the most frequent exciting cause is exposure to inclement weather. How severe this exposure frequently is can only be appreciated by one who has engaged in public practice among the lower and criminal classes. An accident may be the exciting cause. An habitual drinker, drunk or sober, is injured (perhaps a leg has been amputated), and the case goes on well for thirty-six or forty-eight hours, when the patient becomes nervous, sleepless, has hallucinations, and runs into delirium tremens that will be almost certainly fatal. A similar result may follow a simple fracture or any slight injury. Probably the majority of cases of surgical delirium are cases of delirium

tremens. The delirium tremens may come on in the course of a pneumonia. Other acute diseases sometimes act as exciting causes.

SYMPTOMATOLOGY.—In describing the symptomatology of delirium tremens, it has been found convenient to divide its clinical history into three stages. This division must of necessity be somewhat artificial, and it must not be expected that every case will present the stages in a typical form, especially as recovery may take place at any time in the first, second, or third stage, and death in either the second or the third.

Incipient stage. As the disease makes its appearance the subject becomes restless and does not sleep well. If he falls asleep, his sleep is haunted by dreams that soon awaken him. The minute he closes his eyes hallucinations pass before his mental vision. During this stage he is rational and *fully appreciates the character of the disease that is approaching.* He now truly has the "horrors." He may be tremulous, but usually he has only the slight tremor that follows every debauch. This is not nearly so pronounced as the true tremor of delirium tremens. At any moment he may become wildly delirious and, losing the mental control he still has, pass rapidly into the violent stage, becoming dangerous to himself and others. In the incipient stage the patient also exhibits the usual gastric symptoms that follow ordinary alcoholic intoxication.

The incipient stage may last one or two days, to be followed by the violent stage or by gradual recovery. First attacks rarely go beyond this stage. Probably fully half of the cases of delirium tremens that recover do so at this time. At the City Hospital such cases were called *impending delirium tremens.* These are the cases that Näcke calls *abortive delirium tremens.*

Violent stage. The violent stage begins with the true delirium. Sometimes it is ushered in with a violent epileptiform convulsion. Epilepsy in connection with delirium tremens has often been described, and, of course, delirium tremens may occur in an epileptic; but delirium tremens does not cause epilepsy, whatever hereditary alcoholism may have to do with it.

Convulsions were rarely seen at the City Hospital, although occasionally a patient in the violent stage would be received with a history of having had a convulsion. The convulsion may be exactly like that of epilepsy, with the exception, perhaps, of not having the cry. However, it is not epileptic, but should rather be called epileptiform. The patient may recover from a convulsion and be but very slightly delirious. Soon, however, the delirium increases. Krukenberg considers the convulsion "as an initial symptom of the delirium itself." Moeli states that the epileptic attack increases the gravity of the prognosis.

Rapidly, but perhaps by inappreciable degrees, the visions that the sufferer knew did not exist, become realities to him. The patient starts suddenly, turns his head, listens, or looks about him suspiciously. He may still appear rational and deny having hallucinations, probably because he even looks upon his attendants with suspicion. He becomes violent, struggles to free himself from imaginary foes, and perhaps screams at the top of his voice. Hallucinations, illusions, and delusions, often, but not necessarily, of a persecutory nature, crowd upon his mind. Illusions are now much more frequent than hallucinations. These may be of sight, hearing, or smell. Those of sight are most common, and are probably often connected with changes in the retina and optic nerve. A patient will often be seen going through some definite motion, as if at his work. His hands may move as if he were unravelling some endless skein. I have seen a printer go through the motions of setting type. Sleep is almost impossible.

The tremor is very pronounced. It is quite different from the slight tremor of all drinkers, which is easily controlled by the use of whiskey. The true delirium-tremens tremor is much greater; it is increased by an effort to use the muscles. In severe cases, especially when temperature is elevated, the tremor persists even during sleep. It usually begins in the tongue and upper extremities, and finally also affects the legs. It is most marked in the hands.

The patient, on account of the mental condition, feels no pain from the most severe injury. He throws a broken leg about as if it were sound. The symptoms of a pneumonia are completely masked. There is anorexia, but vomiting is very rare. Constipation is the rule. The temperature is variable. There may be very little fever or the temperature may run up to 104°, or higher, without pneumonia or other complication to account for it. The patient often sweats profusely. The urine is scanty, high colored, and usually contains some albumin. At this time the patient may rapidly wear himself out and die. This is usual in cases with severe injuries or pneumonia. The disease may run a comparitively mild course throughout this stage. The great excitement, however, is not of long duration, rarely lasting longer than three or four days; but at the end of this period the exhaustion does not always lead to natural sleep, as many clinicians would have us believe; it often leads to a peculiar typhoid state presently to be described.

After the violent stage is well developed the prognosis becomes grave. Death may take place very rapidly, the entire disease having lasted perhaps but

two days. Pneumonic and surgical cases usually die in this stage; so also do the febrile cases of Magnan. One fatal case (complicated with simple fracture of the tibia) that corresponded to the description of Magnan was observed.

Typhoid stage. The patient gradually passes from the previous condition into this state. But while this stage not infrequently follows a very violent second stage, it more often occurs in cases that from the beginning have had a more quiet delirium, and, indeed, from the start, have had somewhat of a typhoid character, which became more marked as the disease developed. It is the patients that have been drinkers for years, and perhaps have had many mild attacks of delirium tremens, that exhibit this stage most perfectly.

As this stage develops, the delirium becomes quiet. The patient loses his fear of the hallucinations, nor indeed are hallucinations frequent, if they exist at all. Illusions, however, are very frequent early in this stage, and are not usually of a persecutory nature. The patient tugs at his shackles, and thinks he holds the reins of a team of horses. This illusion is very common. Illusions of hearing are frequent.

The typhoid state gradually deepens. The patient is extremely tremulous. He is never awake, and rarely asleep. He is easy to control, but needs constant watching, just as a case of dementia would. He may get up and wander aimlessly about. His speech becomes more and more of a mumble, and finally entirely unintelligible. When sharply told to put out his tongue he protrudes it slowly. He passes urine and feces in bed or anywhere. Albuminuria is usual. The pulse is weak and rapid. There is always some elevation of temperature, although it rarely rises above 102°, until the end. Cheyne-Stokes breathing is occasionally observed. The conjunctivæ are injected, the eyes watery, and the eyelashes frequently glued together. The pupils are normal, or react slowly.

The patient lies with his mouth open, his tongue and lips dry, and his breath extremely fetid. One of the cases observed developed a parotiditis, probably by infection through the ducts from this foul mouth. The patient usually takes sufficient food. The bowels are constipated.

The subject lies in this condition for six or eight weeks, or even longer. He gradually grows weaker. One day his temperarure runs higher than usual, reaches 104° or 105°, or even higher (in one case 108.2°), and he then dies.

A small proportion of cases recover, even at this stage of the disease. The great majority die. This sequel to the violent stage of delirium tremens, for all that it is hardly mentioned in the literature, is by no means rare. At the City Hospital it was often called alcoholic meningitis. Leptomeningitis undoubtedly does occur with alcoholism as an important etiologic factor, but when it occurs it presents more definite signs of meningeal inflammation. Paralysis of the third nerve occurred in one alcoholic case in which undoubted meningitis was proved at the necropsy.

Näcke describes a type of chronic delirium tremens which coresponds to this typhoid stage. He uses the term typhoid in describing it. The *chronic continued delirium tremens* of Rose may be the same. However, many of the chronic forms that have been described seem to be rather cases of true insanity. The descriptions of these forms are often unsatisfactory.

Diagnosis.—Usually the diagnosis presents no difficulties. The conditions to be excluded are: acute alcoholic intoxication, psychoses made prominent by drink, alcoholic insanity, delirium of infectious diseases, and mania.

The diagnosis of the third stage may be difficult if a previous violent stage has not been prominent, or has perhaps not been observed. In making a diagnosis of delirium tremens in the early stages, it is well to remember that it is the rule for a man to have a rational period between an intoxication and the true disease. It is sometimes necessary to watch a case a few days to exclude alcoholic insanity. The tremor has diagnostic importance, but a slight tremor is usual in all forms of alcoholism.

Prognosis.—Statistics show a mortality of from 2 per cent. to 35 per cent. Probably this variation depends, to some extent, upon what is included as delirium tremens by the various observers.

Of the 132 cases, 2 (while in the typhoid state) were removed by friends. The result in these cases is unknown. The total mortality of the 130 cases was 35.4 per cent. Of 12 cases complicated by pneumonia, 10 died. Of 9 cases complicated by surgical injuries, in only one was the injury a dangerous one of itself. The other injuries were simple fractures (usually of the tibia, or above the ankle), crushed toe, fractured lower jaw, and scalp-wound. Only 2 recovered (the scalp-wound and jaw cases); 6 died in the violent stage, and 1 at the end of a long typhoid stage.

Of the 109 uncomplicated cases, 29 died, *i. e.*, 26.6 per cent. Of the 29 deaths, 20 occurred at the end of the typhoid stage, and 9 during the violent stage. Of the 80 recoveries, 33 took place during the incipient stage, or, in other words, were abortive cases; 7 recovered after the typhoid stage, and forty recovered after the violent stage had commenced, and without going into the typhoid stage. Many of these 40 cases were very mild.

Pathology.—The question as to the pathology of this strange disease is not an easy one to answer.

Autopsies, however, make some suggestions. When death occurs after the typhoid stage, the post-mortem examination shows a wet brain—in fact, a very wet brain. There is serum everywhere, in the ventricles and between the membranes. The arachnoid is so water-logged as to appear gelatinous; it may be faintly cloudy, but it is never opaque. The vessels of the pia are dilated. The brain has a wet, glistening appearance, identical with that of the *wet brain of nephritis*. This condition has often been mistaken for leptomeningitis. It is not a meningitis at all. The difference between an inflammation and an edema need not be discussed here.

In the cases that die during the violent stage, the arachnoid has not so much of a gelatinous appearance, as if, perhaps, the edema were not of so long a standing.

The lungs are also edematous, and especially marked in cases dying after the typhoid stage is a condition of hypostatic pneumonia of a high grade. A piece of the lung will sink in water. This condition is sometimes so marked as to lead to its being mistaken for pneumonia, and the sudden high temperature that occurs just before death gives some color to this idea. Microscopic examination reveals the error. Of course, this condition is practically the same on both sides and is limited to the lower lobes. A cut is smoother than a cut through an area of red hepatization. It should not be forgotten, however, that pneumonia may occur.

The kidneys are probably always affected. In the post-mortems held on the cases observed the lesions were frequently quite extensive. Interstitial nephritis, sometimes of a high grade, was always present, while parenchymatous changes were by no means rare. Large white kidneys were never found. Krukenberg describes the kidney-lesions, both macroscopic and microscopic, at length. His valuable article should be consulted on this point.

The heart was of the usual granular-kidney type. Beginning cirrhosis of the liver was occasionally observed.

The old inanition-theory, that delirium tremens is due to the want of an accustomed stimulus, is rarely advanced now. The arguments that have been urged against it seem conclusive. However, this does not exclude the idea that delirium tremens is a form of cerebral asthenia. By cerebral asthenia may be understood a condition of insufficient nutrition, not that the food needed is alcohol, but rather that the alcohol has interfered with the nutritive processes to an extent making proper nutrition difficult, while perhaps the last intoxication has for a time shut off the nutrition almost entirely. Associated with this view of the pathology is the idea, very commonly held by both physicians and laymen, that delirium tremens does not develop except in men that do not eat while drinking. It seems to me that this idea is founded on insufficient observation and is not entirely correct. The absence of food from the stomach makes the absorption of alcohol more rapid, but surely the deleterious effects of alcohol can and do occur in drinkers who eat. Of course constant drinking interferes greatly with digestion and nutrition.

Undoubtedly the symptoms of delirium tremens do present certain slight analogies with those of nerve-exhaustion, neurasthenia, especially perhaps in the way of the insomnia and the frightful dreams. It seems, improbable, however, that a neurasthenic condition could be carried far enough to produce all of the phenomena of this disease. In cerebral anemia we never find conditions analogous to delirium tremens, unless indeed, accepting the theory of Traube, we consider the symptoms of uremia as symptoms of cerebral anemia and edema.

The toxemic theory, *i.e.*, that delirium tremens is due to a toxic action of the alcohol imbibed (unless a very wide construction be put upon it), fails to explain the phenomena of the disease. No amount of alcohol will produce delirium tremens in a healthy man or animal not accustomed to drink. The symptoms of alcoholic poisoning are entirely different. It is hard to think of alcohol as a cumulative poison. And if alcohol should accumulate in the system, why would its effects differ from those of acute alcoholic poisoning, and why would two months, or even longer, be required to eliminate the poison?

More plausible is the idea that the disease is due to actual changes in nerve-tissues, the results of the repeated insults of the alcohol; that it is similar to alcoholic neuritis. This theory and the one allied to it, that delirium tremens is a form of insanity, is very often suggested. Delirium tremens and alcoholic insanity are far from identical clinically. Changes in the cerebral cortical cells have been described in delirium tremens, but they do not appear to be constant nor indeed frequent.

The symptomatology of delirium tremens strongly suggests that its phenomena are due to retained products of metabolism, poisons that may or may not be eliminated, rather than to chronic organic changes in nerve-tissue. Apparently the kidneys are constantly crippled.

On account of the large amount of kidney-parenchyma in excess of what is ordinarily needed, it is very difficult to draw inferences from the appearance of a kidney as to its efficiency. However, the constant presence of these lesions cannot but exercise some influence on the symptomatology, if, indeed, they do not cause all of the phenomena of the disease.

Fürstner found albuminuria in 40 per cent. of all cases examined. He also reports three cases in

which delirium tremens developed in well-marked cases of chronic nephritis. In these cases there was an enormous increase of albumin in the urine, and casts were also found. He attributes the albuminuria to a transitory hyperemia brought on by alcohol. These observations are very suggestive, as are also the similarities between the symptoms of poisoning in chronic nephritis and the symptoms of delirium tremens.

The eclampsiàs of the two diseases are identical. Delirium is a prominent symptom of uremia. Delusions of persecution are common in *folie Brightique*. It has been suggested that many of the hallucinations of delirium tremens are in reality illusions founded on alterations in the retina. These alterations may be of uremic origin. The tremor seems a specific symptom of delirium tremens. Muscular symptoms, however, not very different, also occur in chronic nephritis.

Osler, in speaking of uremia, says: "In some of these cases a condition of torpor persists for weeks, and even months. The tongue is usually furred, and the breath very foul and heavy." In the records of the Cincinnati City Hospital are to be found accounts of cases which entered in a condition of torpor, and finally died. The diagnosis made, chronic nephritis, was fully substantiated by the post-mortem examination. Yet these cases in every particular, both of symptomatology and of pathologic anatomy, were identical with the condition that over and over again was seen to proceed by inappreciable degrees from a typical delirium tremens.

Death from delirium tremens usually occurs at perhaps a little earlier age than does death in ordinary cases of granular nephritis. The first attacks of delirium tremens, which may occur early in life, are not fatal, being usually abortive cases. This may be because the kidney-lesions are not far advanced. Moreover, it is possible that elimination by organs other than the kidneys is also imperfect.

Many cases of uremia, and the other accidents of nephritis, such as edema of the brain and lungs, come on suddenly after a debauch or unusual exposure, and it is not impossible that the symptoms of delirium tremens may be of a similar nature, brought on by the extra work that the last debauch, with concomitant exposure, or injury, or pneumonia, throws on a pair of already crippled kidneys. It is well known how a chronic nephritis influences the prognosis of a pneumonia or an injury.

Uremia, as we ordinarily see it, and delirium tremens are not identical clinically; and for all that, in certain cases it is extremely difficult to differentiate between the two; yet, usually, does delirium tremens present a specific clinical picture. This is an argument against the theory that has been here suggested. Another point is that while the severe uremic symptoms of interstitial nephritis are usually associated with a great increase of albumin in the urine, all cases of delirium tremens do not have albuminuria.

So, for all the arguments in favor of the theory that has been here suggested, it cannot be said with any degree of certainty that it is the correct one. Further investigation must settle this. But whatever finally proves to be the true explanation of the phenomena of this disease, I believe it will be found that delirium tremens does not, and cannot occur in subjects with healthy kidneys.

Treatment.—The frequent, if not invariable, presence of kidney-lesions, whether these lesions do or do not constitute the essential pathology of the disease, should not be forgotten. It is wise to begin treatment with a purgative, and to keep the bowels freely open throughout the disease. Practice shows the value of this. Diuretics, especially digitalis, have been used, and highly praised. Probably hot-air baths and similar procedures would be of great value, especially in the typhoid stage. I have never seen them used. Such means should be used with the idea of eliminating the toxic principles, whatever they may be.

But there are a number of other indications to be met, and in meeting them we are possibly employing physiologic antidotes, for surely certain drugs seem actually curative. By the proper use of sedatives we can prevent the nervous system from becoming overwhelmed, until time enough has passed for the toxins to be eliminated. And, indeed, it seems that violent nervous disturbances are of themselves injurious and dangerous, aside from exhausting the patient, increasing, perhaps, the very products of metabolism of which we are anxious to get rid. It is not considered safe to allow the convulsions of puerperal eclampsia to go unchecked. Yet no one would claim that the drugs used in checking them remove their cause; but the common opinion is that these drugs are to some extent curative. Surely morphin is so considered by many.

A great many cases of delirium tremens will get well without treatment. These are usually abortive cases. First attacks almost always recover unless associated with pneumonia or injury. A careful attention to the digestive system will hasten recovery. Capsicum, or some similar drug, aids greatly in overcoming a nervousness (present after every alcoholic intoxication) that seems associated with the disturbed stomach.

In the severer cases the stomach-symptoms are not nearly so prominent. Vomiting never interferes with medication. Little can be done for the anorexia.

. It is often impossible to tell whether a case in the incipient stage will stop or go on to more dangerous conditions. A radical treatment at this time is easier, safer, and more successful than later. Put the patient to sleep before the severe delirium comes on; it is easy now; it may be very difficult later. The earlier that chloral or other hypnotic is used, the easier can its results be obtained. Exhaustion does not assist the drug until the typhoid stage is reached, when the sleep obtained is not natural but a sort of semi-coma, and the time for benefit from the drug has passed; or, too often, the typhoid stage is never reached, and the exhaustion that we had hoped would aid us leads to a coma that rapidly ends in death.

The medical treatment in vogue at the City Hospital, when I was interne, was potass. brom., gr. xxx; chloral, gr. xx, every three hours—sometimes a little more and sometimes a little less. Very little else was used in the violent stage until the heart began to fail, when, of course, stimulants were administered. The results were not good. Bromids are absolutely worthless in such a disease. At the best their sedative action is a very mild one. Chloral was usually given in altogether insufficient doses. If the chloral or other drug does not make the patient sleep, it does no good and probably does harm.

In a few cases chloral was given in sufficient doses to produce sleep; 30, 45, or 60 grains, varying with the case, were given from every half hour to three-quarters of an hour, until the patient was asleep, and then if he was delirious on waking he got another dose, 30 grains being usually sufficient at this time. The cases so treated did remarkably well. When the treatment was commenced early, but small doses were required. One dose was often sufficient; more than three were never required. The patient often slept eight or ten hours without waking, and on waking was rational. Some of the cases so treated were very severe, one being complicated with a fractured jaw; yet all recovered. Of course, the unusually good results obtained were, in a measure, accidental. This treatment was not sufficiently used at the City Hospital to be very good evidence in favor of such dosage. In all, ten cases were so treated. But while this number is very small, it must be remembered that the results obtained by this treatment in former times were good. One great advantage this method has over repeated small doses is that the patient is not so often disturbed. It is often very difficult to persuade a violent delirium-tremens patient to take medicine after the first two or three doses. Hypodermatic medication alarms the patient too much.

In pneumonia the tendency to heart-failure is so great that perhaps chloral would be dangerous. However, recoveries under any treatment are rare. Perhaps it is especially in surgical cases that this treatment is most valuable. In these cases the first intimation of delirium should be met by sufficient chloral.

Unfortunately many cases will die, no matter what treatment is used. It is astonishing how rapidly some of these cases, especially surgical ones, grow worse in spite of all efforts of physician or surgeon.

Shackles are a necessary evil. In the violent stage they are often indispensable, the milder substitutes, such as tying a sheet over the patient and to the bed, being altogether insufficient. In the later stages it is bad practice to use them, as they tend to keep the patient in one position and increase a tendency to hypostatic pneumonia.

A number of drugs were tried in the typhoid stage. Ergot had no effect. It was used with a mistaken idea as to the pathology. Digitalis seemed of some value, but did not accomplish much. Whiskey was used without very satisfactory results, a much better heart-stimulant being found in strychnin. Some clinicians use whiskey quite freely throughout the disease. I am inclined to doubt the propriety of this. Strychnin is a most valuable drug in the typhoid stage, and indeed in every stage of the disease. It should be used very freely.

Patients in the typhoid stage should not be kept in one position. Possibly something might be accomplished in some cases by getting the patients out of bed occasionally. This, of course, should be done carefully.

The constant watching required through the many weeks that these cases often last is very exhausting to both physician and attendants, and is too liable to result in carelessness. Perhaps the greatest difficulty in treating delirium tremens is to persuade the attendants that the patients are really human beings, suffering from a disease.

THE DIAGNOSIS AND PROGNOSIS OF ALBUMINURIA, INDEPENDENT OF NEPHRITIS.[1]

BY W. H. WASHBURN, M.D.,
OF MILWAUKEE, WIS.

VON HELMONT, a follower of the celebrated Paracelsus, and one of the founders of the Iart-Chemical School of Medicine, in the seventeenth century, thought that the cause of dropsy was *some* fault with the action of the kidneys.

Cotunnius, or Cotugno, in 1770, was aware that the urine, in cases of dropsy, would coagulate upon the application of heat. Following Cotunnius, Blackall, of Exeter, England, made a study of albuminuria, but owing to his comparatively limited facilities for post-mortem examinations, he failed to discover the true seat of the disease and expressed the opinion that it was "due to the elimination of the dropsical fluid by the urinary passages." The opinion thus expressed by Blackall may be regarded as the last expiring gasp of the old "humoral pathology" which, with more or less prominence, had cropped out in the philosophic speculations of most of the *schools* or *systems* of medicine with which the world has been blessed (or otherwise) since the days of Hippocrates.

The great Scotch pathologist, John Hunter (1728–1793) struck at the foundation of these speculations when he deductively assumed that disease is seated in the solids of the body rather than in the fluids. But humoral pathology received its death-blow when Bichat, the "father of general anatomy," by his indefatigable industry, opened a new era in medical science by directing the attention of students to the *tissues* of the body, thereby laying the foundation for the sciences of histology and pathologic anatomy. The labors of Bichat were brought to an untimely close in 1802, but the impulse that he gave to the prosecution of researches in morbid anatomy is still felt.

Richard Bright, pathologist to Guy's Hospital, following the line of study pursued by Bichat, and availing himself of the abundant opportunities for post-mortem examinations at his disposal, forever overthrew the humoral views then vaguely and dimly entertained as to the pathology of albuminuria and dropsy. Bright, although he did not fully elucidate the morbid anatomy of nephritis as we are now acquainted with it, for the first time ascribed the symptoms to physical changes in the structure of the kidneys, and hence there is propriety in associating his name with the disease.

Since the publication of the *Reports of Medical Cases*, in 1827, the names of Rayher, Johnson, Virchow, Rosenstein, Stewart, Gull and Sutton, Tyson, Da Costa, Ralfe, Dickinson, Dukes, and many others have become familiar in the literature of the subject. But although a great mass of information has been the result of the labors of these men, there are still many unsettled questions bearing upon the subject, which time alone can solve. Among these there are none more important than those indicated by the title of this paper. The vast majority of cases of so-called functional albuminuria, or, as I prefer to call them, "albuminuria in the apparently healthy," are discovered when the individual presents himself for examination as a candidate for life-insurance.

We have here, then, to decide whether, in the particular case, the albuminuria is due to a grave organic disease of the kidneys or to a condition dependent upon some slight and transient cause, from which the applicant may recover in a short time. This is a question of paramount importance, from whatever point of view we regard it, but it is one that cannot be satisfactorily answered at the first examination, and probably not at the second or even third.

As regards the urine itself, the main points to be determined are the significance of: First, the amount and persistence of albumin; second, tube-casts; third, specific gravity of the daily urine; fourth, the excretion of urea.

1. *The amount and persistence of albumin.* We can gain comparatively little information as to the nature of the case from a study of this question, for in that gravest of kidney-affections, granular degeneration, the albumin may be very small in amount and may occasionally be entirely absent. Mahomed and others have shown that this disease may even make considerable progress before albumin appears in the urine at all. Bartels,[1] of Kiel, refers to a case of granular degeneration of the kindeys which was under his care for a considerable time and until its fatal termination, in which no albumin was found in the urine at any time. Brannan[2] records a case in which an applicant for life-insurance was found to have albumin in his urine on one examination out of eight, spread over six months. Some months later the man committed suicide, and an autopsy showed commencing nephritis, as well as marked degeneration of the vascular system.

Some writers have thought that the albumin, in cases independent of nephritis, would not be present in a higher amount than $\frac{1}{25}$ or $\frac{1}{20}$ per cent.,

[1] Read before the Wisconsin State Medical Society, May 3, 1893.

but a prominent physician of this city has stated that, while a medical student in college some six or seven years ago, his urine contained a large amount of albumin for some months, the coagulum, on boiling, equalling about one-quarter the bulk of the urine boiled. His urine has now been normal for years.

2. *The significance of tube-casts.* When it was first recognized some years ago that albuminuria did not constitute nephritis, it was thought that when tube-casts were found in the sediment of an albuminous urine, this settled the diagnosis. This view has long since been given up. Da Costa, in his work on *Diagnosis*, speaks of a case in which tube-casts of the hyaline and waxy varieties were found, and in which recovery took place and no indications of nephritis subsequently appeared.

Johnson, Edes, Janeway, Saundby, and others[8] have, from their own experience, arrived at the opinion that "hyaline and epithelial casts are often present in the albuminous urine of patients whose speedy recovery may be confidently predicted." On the other hand, cases of well-developed nephritis may fail, on many examinations, to exhibit any tube-casts.

3. *Specific gravity of the daily urine.* This is regarded by some as one of the most valuable diagnostic indications we have, for the structural changes in the kidneys in chronic nephritis are such that, as Saundby has found, in 70 per cent. of cases the amount of urine is increased, the specific gravity being correspondingly low. Hence, other things being equal, a specific gravity of 1020, or above, of the total daily urine would strengthen the opinion that no grave kidney-disease existed. Da Costa[23] lays special stress on the importance of the specific gravity in the matter of diagnosis, stating that he has yet to see an instance of persistent low specific gravity in albuminuria associated with oxaluria and uric acid, and independent of nephritis.

4. *Excretion of urea.* Dr. C. S. Bond,[4] in a very interesting paper, has brought forward some striking facts to justify his opinion that a diminished average daily excretion of urea is one of the earliest indications pointing to chronic nephritis. Observations have been made by others as to this point, but they are not entirely in accord with those of Dr. Bond, and there are many cases in which the daily amount of urea is normal, or above normal, in which nephritis has been for some time established. Although I have done some work in this line myself, the facts elicited are not of sufficient number to be of any value as data upon which to hazard an opinion.

It, therefore, becomes apparent that we cannot base a diagnosis upon an examination of the urine alone, but must take a much wider view of the case. Before we can conclude that we have to deal with a case of albuminuria independent of nephritis, we must determine the absence of those subjective symptoms which usually accompany that disease, such as gastro-intestinal disorders, neuralgia, rheumatism, and cephalalgia. Saundby found that the pulse-rate in contracting kidney is usually high, ranging from 90 to 100 per minute, though in some cases it may be normal, and that the arterial tension is increased in about 50 per cent. of cases. As cardiac changes, as hypertrophy, appear in a certain proportion of these cases, it becomes necessary in reaching a diagnosis to have reference to the condition of the heart.

Give, then, a case of albuminuria: If upon investigation we find that, though the albumin is present in every specimen of urine examined, it is only in small amount; that the daily quantity of urine is normal, and of normal specific gravity; that the amount of urea excreted is normal; that the pulse is below 80 in frequency, and the heart is normal in size and sounds; that tube-casts are not found, or only occasionally found, in the urinary sediment; that no hereditary predisposition to kidney-disease can be established; that there are neither gouty nor rheumatic tendencies; that the functions of the skin and alimentary canal are active and efficient, it may fairly be concluded that we have to deal with a case in which the diagnosis of albuminuria, independent of nephritis, may be made. And this diagnosis may be adhered to, even if hyaline tube-casts are occasionally detected in the urinary sediment, particularly if the patient is below forty years of age, and crystals of calcium oxalate or uric acid are coincidentally discovered; it being easily conceivable that these substances may initiate such a condition of the uriniferous tubules as to give rise to casts, and which condition may be but transitory, the tubules returning promptly to a normal state.

But just as a cough which may be present in a given case for a more or less protracted period, independently of pulmonary tuberculosis, requires careful treatment, so do these cases of albuminuria, independent of nephritis, and the one case can no more be regarded as physiologic than the other.

Second only in importance to diagnosis is the question of prognosis, and this has reference not only to the immediate future of the case, but also to the remote future—that is the question as to the prospects of recovery from the immediate condition under consideration, and whether there is a greater tendency on the part of individuals thus affected to develop later in life the graver forms of kidney-disease.

On a superficial view we should be inclined to think that the prognosis for the immediate future

would be good, especially in cases in which the albuminuria is more or less intermittent in character, and less favorable when the albuminuria is persistent; and that as to the remote future, we might reasonably expect that among persons whose kidneys had exhibited impaired function on various occasions, and for different periods of time, there would develop an exceptionally large proportion of cases of chronic kidney-disease of a fatal character.

As to the first part of the question, we may perhaps assume to be in a position to speak with a tolerable approximation to definiteness. When albuminuria has been definitely shown to result from diet, muscular exertion, or exposure to cold, the prognosis is decidedly good for the present; and in the so-called simple persistent albuminuria the immediate prognosis is good; but should the case continue for a protracted period, the fear must ever be present that it will eventuate in the development of grave organic changes in the kidneys.

Grainger Stewart[6] says that his observations have led him to conclude that this is not a very frequent termination, but still it is one that is always to be feared, and that a careful watch should be maintained for indications pointing in that direction. Purdy[6] is distinctly of the opinion that persistent albuminuria depends on a pathologic condition of the kidneys, and is therefore of no light import. Roberts[7] expresses a rather decidedly favorable prognosis, but quotes Dr. G. Johnson and Dr. Dukes as being inclined to think that the condition may eventuate in nephritis.

Dr. G. Johnson[8] believes that the long-continued percolation of albumin through the walls of the Malpighian capillaries may result in decided pathologic changes to such an extent that albumin permanently escapes with the urine, "and in consequence of the long-continued filtration of albumin amongst the gland cells of the convoluted tubes, these structures may by degrees become so disorganized as to be incapable of discharging their excretory function." He further says[9] that these so-called functional albuminurias are often the prelude to a permanent and dangerous affection, and that proper hygienic care and watchfulness, together with attention to diet, are called for in order to postpone the grave form of disease.

Rabagliati[10] says that he is entirely out of sympathy with those who are disposed to take a favorable view of cases in which even a trace of albumin is present. Dukes[11] takes a distinctly unfavorable view of the prognosis when the albuminuria has persisted for any length of time. He says: "If the hyperemia be prolonged, however slight in degree, the albuminuria gradually becomes persistent, owing to the permanent dilatation of the bloodvessels, and tends to the destruction of the kidneys." Dr. J. W. Brannan[12] expresses his belief that all the forms and varieties of the so-called functional albuminurias will, unless arrested, ultimate in structural changes in the kidneys. Dr. Lewis,[13] of Hartford, Conn., from a study of vital statistics and the records of life-insurance examinations, infers that from 30 to 40 per cent. of cases of albuminuria terminate fatally. Dr. W. B. Davis, in a valuable contribution to this subject, read before "The Association of Life-Insurance Medical Directors," at its meeting in New York in 1891, refers to the records of the rejections by a certain, not specified, insurance company, on account of the condition under consideration for the years 1877, '78, '79, and January, 1880. The total number of rejections was 137, and of that number 57 had died by 1891; 11 per cent. died of nephritis and about 6 per cent. of heart-disease. Dr. Drysdale,[18] of London, regards the presence of albumin in the urine as a danger-signal, and has expressed the opinion that the man who had habitually or intermittently albuminuria, should make his will, if he had any property, and be prepared for any sudden illness; which, however, he thought might be avoided by a judicious diet and regimen. Dr. Sturgis,[20] in summing up his conclusions as to the value of albuminuria as a means of diagnosis, says that when present, no matter if it be in small quantity, it is always a danger-signal, and, when persistent, indicates some serious organic lesion somewhere. Dr. R. T. Edes[21] refers to Munn's observations, which go to show that many cases of albuminuria, when followed out carefully, are found to develop nephritis. Four of his sixty-nine cases died of this disease in three years.

On the other hand, there are recorded the opinions of such men as Saundby, Klemperer, and Senator, quoted by W. B. Davis in a paper read before the American Medical Association in 1890, to the effect that albuminuria is a source of no danger to life and does not become transformed into serious disease of the kidney. Keating[14] likens this condition to that of an ordinary "cold in the head," and says it has the same consequences. Maguire[15] divides albuminurias into two classes, those with high-tension pulse and those with pulse of low tension, and expresses the opinion that some of the latter might occasionally be accepted for life-insurance. Dr. Pye-Smith[16] believes all these so-called functional forms of albuminuria to be pathologic. He compares albuminuria with hemoptysis, which, though always serious, does not necessarily indicate grave organic disease, and is disposed to take a favorable view of the prognosis if nephritis is not actually established. Saundby[17] thinks cases called by Pavy cyclical albuminuria are insurable lives, and that there may be other forms of these cases at present badly defined which are equally insurable.

Dr. George Harley,[19] of London, does not consider the presence of albumin, whether temporary or permanent, as dangerous *per se*, but regards the prognosis in cases in which the specific gravity is not below 1.015 as good. Dr. Hingston Fox[22] thinks that, when a small trace of albumin is unexplained and all other elements in the life are perfectly sound, such cases are eligible for life-insurance, and that even when it can be shown that the albuminuria is toxic, or due to strain or shock, the cases might be accepted, rating up such lives a few years.

My own experience and observations of this affection, though not extensive enough to warrant any sweeping generalizations, are nevertheless offered for what they are worth, and tend to confirm the opinion tentatively advanced in an earlier portion of this paper, namely: that we might reasonably expect that, among persons whose kidneys had exhibited impaired function on various occasions and for different periods of time, there would develop an exceptionally large proportion of cases of chronic kidney-disease of a fatal character.

Between April, 1886, and January, 1893, in the course of examinations for life-insurance, I have encountered 39 cases of albuminuria. In these the average age was 36 years. According to the American Experience Tables the rate of mortality at the age of 36 years is 9.09 per 1000 per annum. Of my 39 cases of albuminuria, 4 have died, 3 of nephritis and the fourth of pulmonary tuberculosis. This is at the rate of 17.54 per 1000 per annum. This mortality-rate bids fair to be increased in the immediate future, for 4 more of these applicants have for some time been showing evidences of impaired health, one of them being in a decidedly bad state of health at present, having recently suffered a stroke of apoplexy.

It will be observed that the mortality among my cases of albuminuria has been nearly twice as great as the normal mortality.

I think, then, it is fairly safe to conclude that there is no such thing as functional albuminuria; that in every case it is just as much an abnormal condition as a nasal catarrh or as hemoptysis and should receive treatment accordingly; that while, in the individual case, we may feel justified in indulging the hope of ultimate recovery, we must not regard the condition as of such trifling import as to be passed lightly over, and must admit the fact, which seems fairly well established, that, other things being equal, the prospect of longevity is not as good for the albuminuric as for the individual who does not show this condition.

805 GRAND AVENUE.

QUININE-BLINDNESS.[1]

BY KASPAR PISCHL, M.D.,
OCULIST TO THE FRENCH HOSPITAL, SAN FRANCISCO, CALIFORNIA.

ON October 10th, a man, led by his wife, entered my office with the uncertain step of a blind person. As I tried his vision, I found to my astonishment that he had nearly normal sight. The examination of the field of vision solved the puzzle. In both eyes the field of vision was contracted to five degrees; it can be easily understood that an eye with such a small field of vision cannot see the way very well.

The patient, forty years of age, was in a flabby and relaxed condition. The physical examination of the viscera was negative; the urine was free from sugar and albumin. Both eyes, viewed externally, appeared normal. The pupils, in moderate light, were 2.5 mm. in diameter, motionless to light, but slightly acting in accommodation. Central vision: R. E. = 6/6; L. E., 6/9. The man read with plus 5 D., 15/25 and 60/130, but saw only one small word at a time. The field of vision was contracted to five degrees. The ophthalmoscopic examination revealed the optic discs pale, the borders not sharply defined, the bloodvessels about one-third the normal size, and some were bordered by white lines.

As we know by experiments and practice that strychnine heightens the susceptibility of the senses and widens the field of vision even in a normal eye, I made hypodermatic injections of this drug, one-sixtieth grain, and increasing the dose to one-sixth, injecting altogether two and three-quarters grains in twenty-six doses. I also applied the constant current, three milliampères, the anode over the eye, the kathode on the neck, for fifteen minutes daily.

On November 13th—that is, one month after the beginning of the treatment and nearly two and a

[1] Read before the California Academy of Medicine.

half months after the onset of the affection—the field of vision for white was nearly normal, but the field for colors—blue, red, and green—was still contracted to three degrees. On November 23d the latter was increased to one-half of the normal size

As the patient had been a periodic drinker before, I examined with special care for a central scotoma for red and green, which characterizes alcohol-amblyopia and tobacco-amblyopia, but none was to be found.

The last examination, January 30th—that is, about five months after the attack—showed hardly any changes. The field of vision for white was still nearer the normal; the optic disc was more sharply defined.

The previous history of the case is as follows: The patient, a barber, for many years a periodic drinker, had never had malaria, nor had he ever taken quinine before. On the 30th of August, 1892, he fell sick, and called in the physician who was kind enough to send me these data. The patient suffered from a severe attack of malaria, with a temperature at 106° and a very small, quick, jerky pulse. Ten three-grain doses of phenacetin brought the temperature down to 100°. The man was then given ten quinine powders, five grains each, to be taken every three or four hours. After taking three powders the patient complained of deafness, but continued until he took three more doses—that is, in all thirty grains in twenty-four hours. The next morning he awoke totally blind. After he had taken four more of the powders the physician put him on Fowler's solution, with benefit to his general health.

Before speaking of the literature of quinine-poisoning, I would like to relate some experiments made for the purpose of studying the influence of small doses taken for a long time. Dr. Schulz,[1] of the University of Greifswald, gave to ten healthy students from one-twelfth grain to one-third grain of quinine daily for nine days, doubling this dose in the following two weeks. These small doses caused some slight affection of the brain, produced neuralgia of the fifth nerve, irritated the digestive organs, increased the quantity of urine; but they showed the greatest influence upon the circulation in accelerating the action of the heart. The tonus of the bloodvessels themselves appeared diminished, as the puffed-up face and congested conjunctiva proved. It appears that acceleration of the heart-action as well as the tonus of the vessels were varied. Even these small doses showed an effect on the ear and eye; signs of hyperemia followed, with buzzing in the ears, conjunctivitis, and "flickering" before the eyes.

Barabaschen,[2] of the University of Charkow, made experiments with larger doses, beginning with 0.3 and 0.6 grm. of quinine hydrochlorate. This dose had not much effect; in some it produced symptoms of intoxication, acute gastritis, anemia of the brain, pallor of the face and the mucous membranes, dizziness, sometimes to fainting; drowsiness, ringing in the ears, contraction of the retinal vessels, pallor of the optic discs, concentric contraction of the field of vision, deficiency in sight up to temporal amblyopia. Besides this he noticed (1) a marked improvement of vision lasting a few hours; (2) narrowing of the pupil lasting only a short while, and passing into dilatation; (3) acceleration of the pulse followed by retardation; (4) heightening of the sensibility of the skin, which after a short while gave place to diminished sensibility; (5) a small rise of the temperature, followed by the usual fall. In one case he observed blindness of half a minute, returning ten times at intervals of from five to ten minutes. Between the attacks the sight was normal.

Rogers[3] asserts that after the ingestion of twenty grains of cinchonine sulphate the following phenomena may be pretty constantly observed: In about one hour there will be found cardiac weakness and irregularity, and much debility with tremor. Paresis of visual accommodation progresses to such an extent as to be almost complete, in many instances at the end of the second hour; at this stage even the emmetropic eye will require the aid of a 10 D. convex glass to properly distinguish objects at the normal near-point. This paresis, he says, lasts eight or ten hours. Probably the great majority of cases of amblyopia escape observation and record.

The first case of quinine-amblyopia was reported in 1841 by Guacomini. Dr. I. E. Atkinson,[3] of the University of Maryland, in a paper read at the Fortieth Annual Meeting of the American Medical Association, June 25, 1889, very conscientiously and ably collected from the literature of the subject forty-eight cases of quinine-blindness and added one of his own observation. Since that publication I have found five other cases reported by Mellinger,[4] Herbert,[5] Garafolo,[6] Barabaschen,[2] and De Schweinitz.[3] Besides these there are about ten cases mentioned in the literature, without particulars. It would take too much time to go into details about all these cases, interesting as they are. I will therefore give only a short summary of them.

The blindness in these cases was mostly absolute; in some there was only amblyopia of varying degrees. The blindness generally sets in suddenly, "as though you had turned out the gas;" in many cases, however, vision fails gradually, so that it takes a few days before blindness is total. The duration of total blindness, the absence of all perception of light, varies within wide limits—from a few hours or a day or more to several weeks. In one case (Dewey) it lasted three months. In all cases sight was restored, though slowly, and nearly always imperfectly. Central vision returns first; the color-sense is restored later. In some cases the diminution of

the sense of light is permanent. The field of vision, which is extremely contracted, enlarges slowly and probably does not wholly regain its normal extent.

As variations which have been observed, I may add: anesthesia of the cornea, observed by Dr. Voorhies;[3] convergent strabismus, and nystagmus. Passing to the objective symptoms, we find in quinine blindness the pupil dilated and unresponsive to light. In my case, in which I found nearly normal central vision, the pupils did not respond to light, but to accommodative efforts. The opthalmoscopic examination revealed pallor of the optic discs and extreme diminution of the retinal vessels. In Voorhies' case there was no trace of the optic-nerve vessels; nor did they reappear, in the right eye at least, though the patient could read fine print. The bloodvessels generally remain smaller than normal; the color of the disc does not become normal, but often turns quite white. Dickinson[3] noted marked congestion of the retinal and choroidal vessels, together with a remarkable condition of the optic disc, which appeared swollen and pushed forward prominently into the vitreous. The appearance was very similar to that of the condition denominated "Stauungs-papille" choked disc, the usual concomitant or resultant of "neuro-retinitis." This is a striking variation from the otherwise universal experience, and it may not be impossible that the symptoms in this case were expressions of malarial intoxication such as are occasionally observed. In cases examined early with the opthalmoscope a whitish haze, with cherry-colored spots, has been observed at the macula, as in cases of embolism.

The pathogenesis of quinine-amaurosis has been elucidated by recent experiments on dogs by De Schweinitz,[7] of Philadelphia.

A brief summary of these researches shows that: "Quinine, given hypodermatically to dogs in quantities varying from one grain to four grains to the pound, produces blindness in from three to fourteen hours, the earliest appearance of the blindness after the injection being three hours. The ophthalmoscopic picture in these animals was, in all instances, similar to that which has been noted in human beings suffering from quinine amaurosis.

"The microscopical examination revealed thickening and changes in the walls of the central vessel (endo-vasculitis), organization of a clot, the result of thrombosis, an organization which has been carried on even to the extent of its being channelled by new vessels; widening of the infundibulum of the vessels as the result of the constriction of the surrounding nerve-fibers, presenting appearances not unlike a glaucomatous excavation; and, finally, practically complete atrophy of the visual path, including the optic nerves, optic chiasm, and optic tracts, as far as they could be traced. It seems, then, very likely that the original effect of quinine is upon the vasomotor centers, producing constriction of the vessels; that finally changes in the vessels themselves are set up, owing, perhaps, to an endo-vasculitis; that thrombosis may occur, and that the result of all these is an extensive atrophy of the visual tract."

Buller[3] found, by experiments on rabbits, that a galvanic current, applied to the optic nerve of a rabbit, speedily induces a blanching of the retina and nerve similar to that which occurs in quinine-blindness. By some accident he once produced the same picture in the human eye; therefore he thinks that the seat of the morbid changes is the optic nerve between the chiasm and the eyeball. Buller attributes the sudden blindness in cinchonism to a rapid effusion into the lymph-spaces around the nerve, causing an external strangulation, too transient to produce the phenomena of papillitis, but sufficient to bring about edema and blanching of the retina, and a permanent impediment to the blood-carrying capacity of the central arteries.

The dose of quinine sufficient to produce blindness is very variable and largely depends upon idiosyncrasy. H. C. Wood[3] has seen complete temporary blindness follow the ingestion of 12 grains. Nearly always, however, the doses must be very large. Briquet[3] thought that troubles of vision did not occur ordinarily until, for several days, doses of from 23 to 30 grains, or, for a single day, doses of from 45 to 60 grains, had been given. On the other hand, enormous doses sometimes fail to affect vision, though blindness always precedes death when the dose has been fatal. Taussig[3] has recorded a case in which a dose of 1 ounce of quinine sulphate was given to a soldier suffering from ague. The only results were complete deafness and a kind of stupor, followed by recovery.

One case is worthy of detailed report, as it is a typical one, and presents the features of an experiment. It was observed by Dr. Garofolo[6] in Schnabel's Eye Klinik at Graz.

A healthy man took 3½ ounces of quinine by mistake for magnesia. After three-quarters of an hour his head felt heavy, the whole body began to tremble, he vomited, and diarrhea set in; the patient was not able to stand upright. About two hours after he had taken this enormous dose, it grew dark before his eyes so that he could not distinguish faces. The next morning the patient was totally blind, was bothered by loud ringing in his ears, and trembled so that he could neither walk nor stand. Seventeen hours after he had taken the quinine the patient was brought to the eye clinic, where the examination revealed the following: The cardiac sound was dull, but distinct; the pulse small, soft, and slow; both lids were widely opened, the

pupils were dilated, the left *ad maximum* and motionless; both eyes were totally blind. The ophthalmoscopic examination did not show any pathologic symptom. With the right ear loud voices were heard at 1.5 m.; with the left ear, at 3.5 m. distance. The senses of locality, of temperature, and of taste were normal. The sense of smell was deadened. Quinine could not be found in the urine.

Consciousness was unimpaired, but there were hallucinations. The next day no ophthalmoscopic examination could be made on account of the man's mental condition, but on the fourth day the patient was quiet again. At the ophthalmoscopic examination the lateral half of the optic discs appeared very pale; all the arteries and veins of the retina were morbidly contracted. The shifting fog which filled the whole visual area cleared for moments. The patient had, temporarily, vision of 6/43; then every sign of perception of light disappeared again. On the fifth day the central vision of the right eye was 6/8 and he read Jaeger No. 1; in the left eye, 6/36, and he read Jaeger No. 9. The field of vision was contracted upon all sides, but broadened on the following days. The field of vision seemed to the patient to be filled with a whitish, shifting fog, through which objects placed before him became visible only after fixing his eyes upon them for a few seconds, and were again engulfed by the fog, after having been viewed for a while. This condition prevailed until the end of the fourth month. The pallor, first confined to the lateral half, later spread over the whole optic disc and remained so up to the date of dismissal. The size of the bloodvessels also remained stationary.

The veins showed an interesting phenomenon. From the sixth day all the veins of the retina seemed to be filled with very fine grains of blood, between which appeared light spaces. This appearance could be traced to the finest branches, and has been observed in diseases in which there is diminution in the quantity of blood in the retina, especially in embolism of the central artery. Schnabel showed that it can be produced in the normal eye by pressing the ball.

This phenomenon, in connection with the contraction of all of the vessels of the retina, proved that an abnormally small quantity of blood, under diminished pressure, and with diminished velocity, passed the vessels of the retina. Dr. Garofolo draws from this the conclusion that quinine-blindness is caused by ischemia of the retina. This insufficient supply of blood explains why the retina tires with such extraordinary rapidity. But there must, he thinks, be still another operating factor. The blindness has been observed by Graefe with normal ophthalmoscopic appearances, whereas different authors have noted full restoration of vision, though the vessels of the retina remained contracted.

I close with Dr. Atkinson's words: "Without doubt, immense doses of quinine are frequently taken without disastrous consequences, and, while blindness may always be expected in cases of lethal poisoning, it is impossible to fix within definite limits the non-lethal doses that may be expected to induce it. Unquestionably it largely depends upon idiosyncrasy; and, although it hardly ever develops except after the injection of large quantities of the drug, and even then with the greatest absolute rarity, the results are so terrible that even the remote possibility of its occurrence should have an influence in placing some check upon the lavishness with which quinine is too often used in the treatment of disease."

CLINICAL MEMORANDA.

MASKED ENTERIC FEVER.

BY PHILIP K. TAYLOR, M.D.,
OF KINGSTON, RHODE ISLAND.

IN the autumn of 1888 I was called to a case of severe cephalalgia in a young woman who had recently been married. I found a fairly well developed woman of twenty-one years, well nourished, of neurotic temperament, suffering from headache, which she stated was of monthly occurrence. Inquiry developed the following facts: At the age of four or five years she had scarlet fever, after recovery from which it was discovered that the vagina had become closed. The subsequent history was uneventful until the age of fifteen or sixteen, at which time she began to have headaches, soon recurring regularly every month and lasting from twenty-four to forty-eight hours. Treatment apparently had failed to lessen the duration or severity of these attacks.

With the headaches was associated acute pain in the breasts, with some swelling and tenderness. Rarely was there any abdominal soreness, and there had never been any abdominal enlargement. She had never had anything which could be considered as a vicarious menstrual discharge. Examination showed only a shallow cul-de-sac at the mouth of the vagina. The labia were normal in size and appearance, and the mons veneris well developed and covered with hair. The mammæ were well developed and normal. At this time the headache seemed to be relieved by caffeine and atropine.

For several months subsequent to my first visit I was called on to relieve these headaches, and during this time the question of an operation for the atresia was considered and advised. It seemed to me that should the making of a new vaginal passage fail to develop a rudimentary uterus, it would at least offer the means for an approximately normal sexual congress, which the married condition seemed to render necessary.

On June 11, 1889, the headache (unusually severe) was associated with an eruption noted on my record as "nettle-rash." On the 14th instant I was called again. Headache was still present, but not severe. The rash had entirely disappeared. There was rather marked debility, for which a tonic was prescribed. That night she had severe cramp in the calves of her legs, and it took several doses of morphine sulfate, gr. ⅛, atropine sulfate, gr. $\frac{1}{60}$, to relieve it. On the 19th I was called to prescribe for a diarrhea which had troubled her for about twenty-four hours. She had no fever, no headache, and there was no abdominal tenderness. Salol and Dover's powder controlled the diarrhea so effectually that on the 23d I was obliged to order laxatives, giving at the same time elixir ferri, quininæ et strychninæ, ʒj t. i. d., as there was little appetite and her debility persisted. On the 29th backache was complained of over the kidneys and there was slight fever, and on the next day she had pain and soreness all over, the pain being most marked in the head and loins. On July 1st nausea and headache seemed to be her only trouble, and in spite of treatment these continued until the 4th, when the nausea ceased, but the cephalalgia grew worse; she also grew slightly feverish and very nervous and irritable. The temperature was highest on the mornings of the 4th, 5th, and 6th, falling to normal in the afternoon and evening. At its highest in the mouth it was only 100.5°. On the 6th the mouth was sore and contained several patches of canker.

From the 8th to the 10th Mrs. S. was greatly troubled with insomnia, for which bromids were given, combined with the tincture of digitalis. Her strength was not very great, but nothing pointed to any immediate danger. At noon of July 11th I was hastily summoned and found her in imminent danger from heart-failure. Prompt administration of digitalis and whiskey hypodermatically caused her to rally. She was then put upon tr. digitalis, gtt. ij; tr. nucis vom., gtt. iij; whiskey, ʒjss, every hour in milk. At this time her pulse, irregular and thready, averaged 120, and her respiration was 40, shallow and sighing. She continued in this condition, dozing lightly, but rousing to take medicine and nourishment, until July 13th. During this time the digitalis failed to affect the pulse-rate, and she had several acute exacerbations of heart-weakness. At 8 A.M. of the 13th her pulse was 150; respiration 42, shallow and grunting; temperature 103°. She failed gradually, and died at 6 A.M. of the 14th. During the last three or four days she was slightly delirious. Suspicion of typhoid fever was entertained once or twice during the second and third weeks of illness, but entire lack of abdominal tenderness and tympanites, and the irregularity and low range of the fever caused the suspicion to be dismissed. The abnormal physical condition and the coincidence in point of time of her commencing illness with her monthly disturbance gave the sexual cause the preference as the explanation of the sickness. Two days before the death of the patient, feeling again that there was a possibility of a masked case of typhoid, I called Dr. H. K. Gardiner in consultation, and he concurred with me in that diagnosis. Throughout the course of the disease, tonics and easily-assimilable food had been given regularly, and every effort made to conserve the patient's strength. Otherwise the treatment was purely symptomatic.

An autopsy made two hours after death, by Dr. Gardiner and myself, revealed the following interesting conditions: On separating the labia vaginæ no vagina was found. What seemed to be the urethra proved on closer examination to be a blind pouch about 1 centimeter deep and the same in diameter. Into the anterior portion of this pouch opened the urethra, which was normal in size and appearance and also in its relation with the other parts of the pelvis. The labia were of normal size. On opening the abdomen the mesentery was found normal in appearance, containing a moderate amount of fat. A few of the mesentric glands were slightly inflamed. The peritoneum showed no signs of disease. The intestines were distended with gas, but contained no feces. In the ileum were well-defined ulcers limited to Peyer's patches. Other Peyer's glands seemed to have recently healed and one or two were congested and swollen. It may be said here that the possibility of miliary tuberculosis of the abdominal organs or tuberculous ulceration of the intestines was borne in mind during the autopsy, and that no signs of the former could be detected, and the ulcers found in the ileum were unmistakably typhoid. The spleen was somewhat enlarged and congested. The liver and kidneys appeared normal on section. As the patient had had no cough and no symptoms of any pulmonary disease, we yielded to the objections of the husband and left the thorax unopened.

The uterus was four cm. long externally and had an external diameter of one cm. There was apparently no uterine cavity. The vagina was represented by a ligamentous membrane about seven mm. in thickness. The Fallopian tubes and the ovaries were normal in size and appearance, except that the right ovary contained a small cyst about the size of a bean. We were unable to remove the parts for microscopic or other examination. The other cavities of the body were not opened.

It is of interest to know that the mother of this patient had atresia vaginæ following a fever, and was successfully operated on for the restoration of the passage. Operation had been urged in this case, and it is a question of much interest whether such an operation performed at the age of puberty would have led to the development of an arrested uterus and made a sexually perfect woman. Another question raised by this case is the moral right of such a woman to marry. In this particular case the man was fully aware of the woman's imperfections previous to the marriage; but even so, is not such marriage liable to lead to marital infidelity, or to repulsive abnormal sexual gratification? In regard to the typhoid fever I can only say that it is the most misleading case I have ever seen in a practice of over ten years.

SYNDACTYLUS.

BY A. L. BENEDICT, A.M., M.D.,
OF BUFFALO, N. Y.

THE following case I am enabled to report through the courtesy of Dr. Marcell Hartwig, who very kindly invited me to assist at the operation, and to make an examination of the anatomic condition.

The patient was a child, six days old, that presented the following peculiarities. Of the left hand the metacarpal bone and phalanges of the thumb were normal.

There were two other metacarpal bones and fingers. The proximal and middle phalanges were separate, so far as the bones were concerned, but the skin was united in a web, with a distinct crease beneath the bones. The distal phalanges inclined toward each other, and blended into one broad, bony mass. The nails were completely fused, showing a broad half-moon. The joints were movable, except in so far as they were limited by the obliquity of the distal phalanges.

The right hand, at first sight, appeared to be a second left hand without a thumb, but having three fingers. Closer examination showed that the little outer digit had only two phalanges, and was, therefore, a thumb. It was separated from the index finger by a cleft extending to the base of the nails, and by a web reaching half-way down the proximal phalanx. Below this point the fleshy union was almost complete. The remaining digit had also a separate nail, and was without bony connection with the index finger. The soft parts, however, were closely united throughout their whole extent. There was not even a web, only a deep dorsal crease, to separate the two fingers. On account of this crease the dorsal aspects of the fingers slanted toward each other, making an angle of 135°.

The left foot was normal, except for an unusually wide separation of the hallux from the lesser toes.

The right foot had four metatarsal bones and digits, the missing member being apparently the second toe, for the hallux was remote from the three other toes. The next two toes, corresponding to the third and fourth of a normal foot, had a web extending the length of the proximal and middle phalanges.

There was also an antero-posterior angle in the lower third of the right tibia, presumably due to an intra-uterine fracture. The mother had fallen down five steps two or three months before confinement, striking on her back.

The child was, with the exceptions noted, well formed and healthy. There was nothing to account for the anomalous development of the feet and hands. The parents were healthy young Germans, who had had two previous children without deformity, and no history could be elicited of any malformation in either family. The parents ascribed the deformities to a maternal impression. When about five months pregnant the mother had an altercation with a peddler, who startled her by suddenly holding up before her a mutilated hand.

The operation was conducted under chloroform-anesthesia, lysol being the antiseptic used. The fingers were separated in the usual manner by the sigmoid skin-flaps, except where the absence of a true web prevented. In these places iodoform-gauze was tucked between the fingers to prevent reunion. Correction of the tibial deformity was postponed, and operation on the toes was considered unnecessary.

HEARING RESTORED BY LARGE DOSES OF QUININE.

BY J. S. TRIPLETT, M.D.,
OF HARRISONVILLE, MO.

THE patient, a man of sixty-two years, is very robust, and has always had very good health. About eight years ago he noticed that the hearing in his right ear was steadily growing less acute, until he finally became absolutely deaf in that ear; the hearing in the left ear remaining normal.

Shortly after the deafness developed both lenses of the eyes became cataractous, the left maturing before the right. Two years ago, in September, the left lens was extracted. All went well until he "caught cold" in the aphakic eye, when severe opthalmitis set in. The pain was so severe that the opiate directed by his physician did not allay it. He told his physician to prescribe for him all the quinine he could stand. The quinine was put into large capsules, and he was directed to take one capsule every four hours; but instead of taking *one* he took *three* capsules every four hours. Cinchonism followed, and a "burning sensation" in the extremities, especially the lower, was experienced. The ocular inflammation subsided, but with loss of vision. With the subsidence of the inflammation hearing returned, and has been normal ever since. There was no discharge from either ear, nor was there tinnitus aurium in either. No cause could be assigned for the deafness. The man had never been troubled with catarrh of the naso-pharynx.

In the following March the remaining cataractous lens was extracted. No complication arose, and the man now has good vision in the eye.

It seems that in this case quinine simply reversed its usual modus operandi. I suppose there is no practitioner who has not seen deafness of varying degrees, temporary or permanent, caused by large doses of quinine.

It is known that quinine produces congestion of the peripheral sense-organs, and it is probable that the auditory organs were in such a peculiar condition that congestion brought about this happy result.

I think it also probable that, unnoticed, a slight discharge may have escaped during the height of the congestion. I do not know the quantity of quinine taken.

MEDICAL PROGRESS.

The Early Diagnosis of Chronic Nephritis.—For many years M. DIEULAFOY (*Lancet*, No. 3643, p. 1542) has sought to emphasize the importance of divers symptoms which, though often apparently trivial, are none the less significant of the existence of that very common malady, chronic nephritis. To these symptoms he has given the name of *petite urêmie* or Brightism. He regards albuminuria as an unreliable symptom of chronic nephritis. Of sixty cases under treatment in his wards during recent years albuminuria was absent in one-fourth. That nephritis really existed was proved in several instances post mortem. In another series of cases albumin disappeared in spite of the continued evolution of the disease. Some patients are albuminuric without being nephritic. Amongst the symptoms of nephritis M. Dieulafoy mentions auditory troubles. These consist in whistling or more sonorous noises in one or both ears, the causes being multiple (edema, paralysis of the acoustic nerve, variations in pressure). The frequency of these noises may be judged of when it is stated that they were present in thirty-four out of sixty cases. Menière's vertigo was

frequently complained of (thirteen times in sixty). Asphyxia of the extremities, first described by Maurice Raynaud, is one of the commonest symptoms of chronic nephritis. This begins as formication of the hands or fingers, and then the tips of the latter become bloodless, pale, and numb. This dead-finger symptom is found in all the forms and in all the stages of chronic nephritis. Itching, without possessing the same importance as the foregoing, is sometimes very severe. Frequency of micturition is well known as a symptom of the disease. To this symptom M. Dieulafoy has given the name of pollakiuria, to distinguish it from polyuria, many nephritics, in fact, urinating ten or twelve times a day without voiding a quantity above the normal. Cryesthesia (κρύος = cold), or sensitiveness to cold, is a minor symptom of nephritis. It is generally confined to the lower extremities. Cramps, especially nocturnal, in the calves of the legs are sometimes severe enough to wake the patient. Epistaxis, chiefly occurring in the morning, is often significant. Electriform shocks must also be counted in this category. At the moment of falling asleep or during sleep the patient is aroused by a single violent shock, recalling the effects of an electric discharge. The temporal sign is frequent. Here the temporal artery is distended, dilated, and tortuous without being atheromatous. This is, of course, due to high arterial tension. The foregoing symptoms, if associated in any one individual, are, according to M. Dieulafoy, sufficient to warrant the diagnosis of chronic nephritis. He is convinced that many persons apparently healthy are in reality nephritic. A confirmation of this diagnosis will frequently be found in the good effects of an exclusive milk-diet, which causes the disappearance of these seemingly insignificant troubles. M. Dieulafoy has also applied another test—viz., the degree of toxicity of the urine passed by patients affected with chronic nephritis. He finds that this secretion has in such cases lost a portion of its toxic properties.

Extensive Sinus-phlebitis Successfully Treated by Removal of the Petrous Portion of the Temporal Bone.—BIRCHER (*Centralbl. f. Chirurgie*, 1893, No. 22, p. 483) has reported the case of a woman, twenty-five years old, who had scarlatina in 1877, which was followed by suppuration of both ears, with total loss of hearing on the left and partial loss upon the right. In September, 1892, she was seized with chills, pains in the extremities, intense headache and mental confusion. The mastoid process and the lateral portion of the neck in the course of the great vessels on the left side became sensitive to pressure, but not red or tumid. On September 8th the mastoid process was opened and offensive pus evacuated. The bony wall of the transverse sulcus was perforated, and between this wall and the membranous investment of the transverse sinus lay a second collection of pus. After thorough evacuation and disinfection the wound was closed and dressed. The patient was temporarily relieved; but on September 11th hectic fever returned. On September 16th the oculo-motor nerve was found to be paralyzed, the pupil dilated, and pain was present in the course of the frontal nerve. On the 19th the abducens and the trochlear nerves were paralyzed. On the following day, after exposure of the bone, two trephine-openings were made, side by side, above the external auditory meatus, and through these the middle fossa of the base of the brain entered. The entire petrous portion of the temporal bone was carefully removed, but not until the apex was reached was a collection of pus found. The parts were now thoroughly curetted, cleaned, and disinfected, and an antispetic dressing was applied. Fever and headache at once subsided. In consequence of the removal of the portion of the facial nerve contained within the petrous bone the left side of the face was completely paralyzed. There was, besides, total ophthalmoplegia, with inflammation, in consequence of imperfect closure of the eye. There was diplopia when the lid was elevated. Accommodation was paralyzed. The fundus appeared normal. There was pain in the course of the first branch of the trigeminus and sensitiveness in the course of the infra-orbital division. Morphine and bromids brought amelioration but not cure. On November 15th the frontal nerve was resected, with entire relief to the pain. Some degree of movement in the left eye had by this time returned. The trochlear nerve and the branch to the levator palpebræ superioris were the last to resume their function. The restoration was but partial in the ocular and in the facial muscles, but by wearing spectacles during the day and covering the eye with a damp cloth at night the woman was able to resume her duties as a farm-laborer.

The Structure and Function of the Mammalian Heart.—As the result of a special research, KENT (*Journal of Physiology*, vol. xiv, Nos. 4 and 5, p. 233) has found that whereas in the past it has been supposed that the mammalian heart differed from the heart of cold-blooded animals, in having a complete break of muscular continuity between auricles and ventricles, it has now been shown that no such break exists, but that the auricles are connected with the ventricles both by strands of altered muscular tissue (especially well developed in the lower mammals) and by a more complex system of branching and anastomosing fibers, which penetrate the fibrous tissue between the two chambers (specially well developed in the higher mammals). Muscular continuity being established, and a variety of observations upon the human heart, such as the study of the reversed beat, the time-relations of the reversed as compared with the direct beat, the time-relations of the beat in animals of different ages, the effects of compression of the auriculo-ventricular groove and the study of the beat in the dying heart, all tending toward the explanation of the transmission of the contraction from auricle to ventricle as a case of simple muscular conduction, the ideas that have been held as to the nervous nature of the transmitting apparatus become less necessary than up to the present time they have been. The results of observations upon the hearts of cold-blooded animals, in which the connective muscular connection has long been known to exist, become to a certain extent applicable to the heart of the mammal, and many of the effects obtained by artificial interference with the muscular structures existing at the groove in cold-blooded animals may be obtained with almost equal ease in the case of the mammal. The passage of a contraction over the auricular wall also has been proved to occur independently of the larger nerves, inasmuch as the contraction can pass over a zigzag strip of tissue made by a series of

interdigitating incisions carried in any direction, and the free application of ammonia to all visible nerves does not arrest the contraction either in auricles or ventricles. The passage of the contraction over the cardiac tissue of the heart then appears to occur as a simple muscular wave, and the transmission of the contraction across the auriculo-ventricular groove appears to be of a similar nature.

Diabetes, with Diabetic Coma, in an Infant Eighteen Months Old.—DUFLOCQ and DAUCHEZ (*Revue de Médecine*, 1893, No. 6, p. 546) have reported the case of an infant, eighteen months old, always well from birth, but for two weeks constipated, in consequence, it was thought, of the use of sterilized milk, of which immoderate quantities (five pints daily) were taken. Within this time the child had become ill-tempered and depressed, and moaned at night. The urine was passed in excess. Notwithstanding its good appetite, the child had become greatly emaciated. The mother attributed the symptoms to difficult dentition, as two canines were about to make their appearance. There was no vomiting. The abdomen was distended with gas. The pulse was feeble, the face cyanotic. On the day after the first observation the child appeared to go into collapse, and became comatose. For the first time the possibility of diabetes suggested itself, but no urine could be obtained. The child could not be brought out of this condition, and death took place. Examination of a napkin that the child had worn disclosed the presence of a sticky powder, which upon solution and chemical analysis proved to be glucose. Two other cases of diabetes in infants under two years of age, in which death took place in coma, have been reported. In these also dentition was in progress. In another case diabetes developed, a few weeks after birth, in an infant that was nourished with corn-starch, a fatal termination ensuing. In one case, in an infant of seven months, diabetes developed four weeks after a fall from the nurse's arms. In some instances heredity seems to play a significant part. Among the symptoms noted in many of the cases was a change in character. Previously bright and good-natured children became morose and ill-tempered. Constipation and abdominal distention were common. The frequency of micturition was increased, and increased quantities of urine were excreted. There were also thirst, pallor, and emaciation. In some cases coma develops suddenly, and some terminate fatally. In other cases death has resulted from asthenia, pulmonary gangrene, broncho-pneumonia, or generalized miliary tuberculosis. Recovery is exceptional, but has been observed. Finally, it is pointed out that the rapidity of course is suggestive of an infectious origin.

Intubation in a Case of Laryngismus Stridulus.—POTT (*Münchener medicin. Wochenschr.*, Jahrg. xl, No. 16, p. 303) has reported the case of a child, a year and a half old, in which impending suffocation during an attack of laryngismus stridulus was relieved by the introduction of a tube into the larynx, in conjunction with the employment of artificial respiration. Neither the beating of the heart nor pulsation at the wrist could be perceived. On account of the abolition of reflex sensibility there was no difficulty in the introduction of the tube, for which purpose, to save time, the extubator was used. After five minutes the heart could again be heard to beat, and the pulse returned at the wrist. The cyanosis soon subsided. In the course of ten minutes more, spontaneous respiratory movements returned. The tube was retained for half an hour, when, on account of irritative cough, it was permanently removed. Other attacks occurred, but none of the same intensity as the one detailed.

Extirpation of Carcinoma of the Pylorus.—At a recent meeting of the Paris Academy of Medicine, DEFONTAINE (*Le Mercredi Médicale*, No. 24, 1893, p. 290) reported two cases in which he had successfully removed the pylorus for carcinoma. One had been operated upon a year previously and the patient had gained 30 pounds in weight. The second operation had been performed a month before. The patient was able to take nourishment on the fourth day; to arise from bed on the twelfth day; and to leave the hospital on the fifteenth day. In both cases the operation was rapidly followed by restoration to health. In a short time the yellowish, earthy appearance was replaced by a clear complexion. The results were more satisfactory than could be attained by gastro-enterostomy, as the orifice of communication between stomach and intestine remained sufficient, and the offending cause was removed.

Spina Bifida Cured by Operation.—WALTHER (*Rev. des Mal. de l'Enfance*, May, 1893, t. xi, p. 193) has reported the case of a child that at birth presented a spina bifida in the sacral region, the walls of which were so thin that immediate operation was determined upon and carried out four hours after birth. By means of a capillary trocar, about seven and one-half ounces of fluid were gradually evacuated. The sac was dissected up and the opening that remained closed by means of sutures. The recovery was excellent, and eighteen months later the child was in good condition and learning to walk.

THERAPEUTIC NOTES.

The Use of Methylene blue in the Treatment of Malaria and Diphtheria.—KASEN-BECK (*Centralbl. f. klin. Medicin*, 1893, No. 25, p. 521) has reported the employment of methylene-blue in the treatment of thirty cases of malarial fever and twelve of diphtheria with entirely satisfactory results.

In the cases of malaria the remedy was employed only when quinine and its salts disagreed, or after these and other drugs, including phenacetin, antipyrin, phenocoll hydrochlorid, ammonium chlorid, tincture of helianthus, eucalyptus globulus, and arsenic had failed. The diagnosis was based upon the physical examination, the blood being examined in only one instance, with the result of finding malarial parasites; the cases were, however, otherwise typical. The patients varied in age from two and one-half to forty years. Three suffered from masked intermittent fever; in one, manifested by trigeminal neuralgia, in another by headache, and in the third by pains in the eyes for five years. It was in the last case that plasmodia were found in the blood. The remaining cases presented intermittent fever of varying type, mostly, however, tertian and quartan. The

duration of the disease had varied from three weeks to a year, mostly, however, from three to six months. The drug was given four or five times a day, at intervals of an hour, in capsules, in doses of 1.5 grains, with 2.5 grains of powdered nutmeg. The paroxysms ceased soon after the institution of the treatment. In only one case did a recurrence take place, for the dissipation of which the solution of potassium arsenite, in ascending doses, became necessary. In five cases vomiting followed the ingestion of the first one or two doses. In most cases there was increased frequency of micturition, unattended, however, with pain. In some cases, in which the nutmeg was omitted, and in some in which full doses (4.5 grains) were given, strangury occurred; in one case hematuria occurred, but ceased after the withdrawal of the remedy.

In the cases of diphtheria a watery solution (1 to 9) was applied to the affected surface two or three times a day by means of a cotton swab. The temperature soon declined; edema and inflammation rapidly subsided, and the membrane was rapidly cast off. The urine became slightly discolored. It is suggested that small doses of the remedy be also administered internally. To facilitate the desquamation of the membrame small doses of pilocarpine (gr. $\frac{1}{25}$ to gr. $\frac{1}{15}$, thrice daily) were additionally prescribed. Recovery ensued in every instance. In three cases paralysis of the palate occurred, and in one of these paresis of the lower extremities.

A Case of Paraldehyde-habit.—ELKINS (*Edinburgh Medical Journal*, July, 1893, p. 39) has reported the case of a man, sixty-five years old, who for seven years had been troubled with insomnia of gradually progressive intensity. On one occasion small doses of paraldehyde were directed and proved useful. A habit was soon acquired, and the doses were rapidly increased, so that after two years and two months sixteen ounces of the drug were being taken in the course of a week. Emaciation became pronounced, and symptoms resembling those of delirium tremens made their appearance. The insomnia was most distressing. There was general tremulousness; the gait was feeble and unsteady, and all movements were slowly performed. The action of the heart was weak and irregular. The pulse was seventy-four, and intermitted every ten or twelve beats, while the volume of the beats was unequal. Flatulence was marked, and the bowels were costive. The breath smelt strongly of paraldehyde. The patient was nervous, restless, and anxious about his condition. An attempt was made to gradually withdraw the drug, but was attended with a good deal of difficulty; the patient developing hallucinations of sight and hearing, and becoming quite unmanageable, and, for a time, refusing all medicine. On a few occasions fifteen grains of sulfonal were given. Finally, gradual improvement set in, and after the lapse of about three months the man was quite restored to health.

Treatment of Gonorrhea.—The line of procedure followed out at the clinic of Blaschko, at Berlin, is thus described by GEBERT (*Münchener medicin. Wochenschr.*, 1893, No. 25, p. 491). In recent cases injections are not used, but instead oil of santal is given six times a day in capsules, each containing 7½ minims. If the patient cannot swallow capsules, the following prescription is given:

℞.—Olei menth. piper. . . . gtt. x.
Olei santal. . . . . ad ℥ss.—M.
S.—Gtt. xv thrice daily.

This treatment will in most cases lead to recovery in the course of three weeks. Should the secretion persist after this time injections may be begun. Of these the best are zinc sulfate, 0.5 to 100, and potassium permanganate, 1 to 200. Subsequently astringents may be employed: tannic acid, 1 to 200, or argentic nitrate, 0.03 to 100. In addition to the local treatment the diet must, of course, be properly regulated. In case of epididymitis recumbency in bed must be insisted upon and compresses applied. In cases of chronic gonorrhea of the anterior urethra injections of argentic nitrate, 1 to 2000, or stronger, are employed. In cases of chronic gonorrhea of the posterior urethra injections or applications of argentic nitrate are made.

Codeine-intoxication.—SPRATLING (*Medical Record*. No. 1184, p. 77) has reported the case of a married woman, who, immediately after dinner, took sixteen half-grain pills of codeine. An hour later nausea appeared, followed by the vomiting of a small quantity of semi-liquid matter. There were marked irritability and restlessness. Convulsive movements, involving the entire voluntary muscular system, but most marked in the upper extremities and in the head, occurred at frequent intervals. There was intense irritation of the skin all over the body, but most annoying on the flexor surface of the forearms and on the back. The surface of the body was warm and dry. The pupils were fixed in pin-point contraction. The respirations numbered twelve per minute. There was complaint of great thirst and an uncomfortable feeling of fulness of the head. After the painful irritation of the skin had been relieved by sponging the body with a solution of sodium bicarbonate, the woman sank into a slight doze, from which she would awake in a few minutes with a start. The skin was hyperesthetic to a marked degree. The usual treatment for opium-poisoning was employed, and in a few hours marked improvement had taken place, leading soon to perfect recovery.

For the Dyspnea of Pulmonary Tuberculosis.—ROBINSON (*Medical Record*, No. 1184, p. 77) recommends a tincture of "rosin-weed," prepared according to the following formula:

℞.—Ext. fluid silphii lancinati (radicis) . f. ℥j.
Spts. vini rectif. . . . . f. ℥iv.
Aquæ . . . . . f. ℥ij.—M.
Filter, Sig. f℥ss–f℥j as a dose.

For Chronic Eczema.—

℞.—Acid. salicylic. . . . . gr. xxx.
Zinci oxidi . . . . . ℥vj.
Pulv. amyli . . . . . ℥vj.
Vaselin. . . . . ℥jss.—M.

S.—To be applied topically daily and not to be washed or rubbed off.—*The Practitioner*.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 29, 1893.

THE DISORGANIZATION OF MEDICAL SCIENCE.

ONE of America's well-known scientists, in charge of an ethnologic exhibit at the Columbian Exposition, was asked if there were no distinctive medical exhibit showing the progress of medical science and art. "Progress of Medicine!" said he, contemptuously. "There is no such a thing!" From further conversation it was clear that, in the opinion of the gentleman, by the term medical science is only to be understood the curing of a sick person in its most restrictive sense. It may be asserted, moreover, that this limited definition is that tacitly agreed upon by the general scientific mind of the day. It is becoming more evident that hygiene, with its hundreds of subordinate departments, and its thousands of meeting-points with human life, is becoming autonomic, so far as medicine is concerned, and that soon hygiene and medicine will not only be possibly distinct callings, but that they will necessarily be distinct. Bacteriology is also tending toward a similar autonomy. In a word, to generalize the two aspects, we may say that preventive medicine and curative medicine are slowly drifting apart, each segregating into distinct fields of study and activity, to be pursued less and less by the same individual. Even the medical profession is in various ways assenting to the breach. It is not uncommon to hear some semi-contemptuous remark about the "laboratory doctor," the "bug-man," or the "sewer-physician."

But it remains an infinitely serious question whether this is a wise movement or not. It may even be held one of the most important things the profession has to ponder and decide about during the next generation. Its significance is manifest in the fact that with the progress in civilization cure must more and more yield place to prevention, so that as all wise minds seek to forefend coming ill, the function of the therapeutist as such must be one of progressively lessening influence, whilst that of the preventer must be one of continuously enlarging influence. If the treatment of smallpox a century ago had been the sole duty of the physician, he would now find himself out of work. Thus as one after another we learn the preventions of diseases, the rôle of the therapeutist becomes more and more sharply restricted with each new discovery.

It may be said that it matters not by whom or by what class of men the work is done, so that the work is in truth done, well done, and so that society receives the protection. In answer, it should be remembered that there is a doubt in the minds of many if the tendency toward differentiation of function in our work of life is not already excessive. Some specialism there must be, even much, but so far as medicine goes it is agreed that all specialists must first have a thorough grounding in general medicine, and that they must well understand the physiologic and pathologic relations of the special organs and objects of their own study with those of other specialists. Moreover, prevention is never absolute, and no disease is, so far as we can judge, ever wholly stamped out. Hence the curers will always have office, and work to do. Prevention, too, not seldom runs, or may run, into pathogenesis, and the sanitarian or bacteriologist must be on the alert to see that prophylaxis shall not indirectly become the origin of disease. He must be a physician to keep from being a disease-producer.

A multitude of weighty reasons at once arise in the mind, all going to show that if the two departments of curative and preventive medicine become separated, each officered and manned by men knowing little or nothing of the work, methods, and ideals of the other, it will be the worse for that society for whose welfare we labor. The consequent narrowing of the physician's sphere of labor and usefulness will serve to further emphasize the contempt

with which the populace already looks upon the doctor-world. Medical sectarianism will be immensely increased by it, and heaven knows that few greater misfortunes could happen than greater popular ignorance as to the value to the world of an enlightened and powerful medical profession, and of the disgrace of medical sectarianism.

Those, therefore, who shape our legislation and mould popular sentiment, should, we think, struggle against the disorganizing tendencies of our science. The work of preventing and of healing disease is essentially one work, and the further apart they drift the poorer will the work be done, the worse for society, and certainly the worse for that part that is content to become, in the ever-narrowing sense of the word, medical. It should never be forgotten that JENNER, KOCH, and LISTER were physicians. It will be a profound professional misfortune if future discoveries and progress in preventive medicine shall be made by non-medical men. Then will the future scientist ask, with all the more reason and justified scorn, "What progress, pray, is there to chronicle in medicine?" The genuine progress in medicine consists, indeed, in making medicine and therapeutics unnecessary. Those who have true pride in their profession will not willingly give up the work that rightfully, and by inheritance, has fallen to them, but while prompt to relieve the present evil and lessen bad results, they will also seek to prevent the coming evil, and to neutralize the causes whence flow the bad results. Sanitary science, bacteriology, and all those biologic studies that go to make up preventive medical science must, therefore, be integral parts of the curricula of every true medical school; the teachers of these branches should be physicians; the boards, National, State, or City, of public health, quarantine, etc., should at least have medical representatives, if not be entirely made up and governed by medical men. Throughout the land every physician should actively interest himself in whatever pertains to the health of the community, thus showing by word and deed that it is our proper function to prevent as well as to heal disease, and that the two things must be done by one person, and by one profession.

A NEW PROCEDURE IN MEDICAL TESTIMONY.

PHYSICIANS have unfortunately frequent opportunities to share, with other busy workers, the exasperations incident to attendance at court. To those not in the law, its dilatory and interrupted methods of business seem inexplicable and even disgusting, and it is not surprising, therefore, that efforts should be made to secure reforms, to which, however, the lawyers are too often opposed. Any progress is of interest, and it worthy of note that the State of New York has recently passed a law designed to convenience physicians and surgeons engaged in hospital duties. The act provides that in suits for damages for accidents to persons, medical witnesses who may have become cognizant of the facts in the course of their service in any hospital may give their testimony before a referee at a time and place to be arranged for each case, and such testimony may be read in court in lieu of the personal appearance of the witness. The trial judge is, however, empowered to order the attendance of the witness. The law applies, of course, to civil actions only. No State law could set aside the privilege guaranteed by the Constitution that a prisoner shall have compulsory process for his own witnesses, and must be confronted by the witnesses against him. The act also limits its operation to hospital cases; it does not extend to one who may see an injured person in the regular course of practice.

Information as to the circumstances that have brought about this somewhat marked departure from legal methods is not at hand, but it was possibly the result of corporation influence. It seems unlikely that a State Legislature, constituted like that of New York, would take such a step solely as a concession to the medical profession. The act will probably operate to the advantage of those corporations, such as steam and tramway lines, which are frequent defendants in suits for injury to persons. In such cases the testimony of the doctor first attending the injured person will usually be unfavorable to the company defendant, and anything that can diminish the vividness or directness of his testimony will inure to the disadvantage of the party by whom the witness is called. Now the interest that a hospital resident or consultant takes in an accident case is usually only as an incident of practice. He is not likely to feel obliged to make a sacrifice of his convenience to assist in securing a heavy verdict for the patient, and will, therefore, take advantage of the opportunity to avoid attendance at court. The defending company is generally wealthy and well equipped for legal battles; good medical talent will be secured by liberal fees, and the testimony in person by such witnesses will go far toward overcoming

the effect of a tedious list of questions and answers read to a jury. It is not improbable, therefore, that judges, recognizing the disadvantage to which the plaintiff is subjected, will send for the witness, at least in rebuttal, and the gain to the medical officer will be slight. On the other hand, the act may lead to the offer of considerable fees to the hospital officer, contingent upon getting them "out of Mr. Pickwick," so to speak, and thus extend the already too frequent practice in this respect.

As already noted, the act does not apply to general practitioners who may see a case in their daily routine. Why this restriction was made it is difficult to determine. In truth, the hospital resident will be probably least inconvenienced by the obligation to attend court. He can generally secure a substitute from among his colleagues, and can arrange to attend to much of his routine duty before or after the hours of court. His absence is in the line of his duty. His patients are almost always under the care of well-trained nurses. The general practitioner has no such advantages. The hours that he will be wasting in court are those that he usually devotes to visiting his patients, and many of these will be without competent attendance other than that which he affords them.

Experience is the only test of legislation, and it will be interesting to watch the effect of this new provision, regretting, however, that if a material departure in the status of the medical witness was to be made it was not in some direction in which relief is more urgent.

CONGENITAL MYOTONIA.

LEYDEN in 1874 first described an affection in which voluntary movement after a period of rest was followed by tonic contraction of the muscles brought into play, the spasm subsiding as the effort was persisted in. Two years later the disease was independently described by THOMSEN, an English physician, himself a victim of the disorder, and in whose family it had existed during five generations. The disease is quite rare, the number of recorded cases probably not exceeding half a hundred. The symptoms commonly appear early in life, sometimes soon after birth; not rarely more than one member of the same family suffers. The lower extremities are usually more profoundly involved than the upper, and the face, as a rule, escapes. The affected muscles in time undergo great increase in size, though they do not become proportionately powerful. The spasm is aggravated by attention and emotion. Sensibility and reflex action present no abnormality. Muscles and nerves exhibit a characteristic electric reaction: response and relaxation are both slow, while voltaic stimulation is followed by wave-like contractions passing from kathode to anode. Treatment has thus far been unavailing. In the absence of autopsies the precise nature of the disease has been uncertain, although examinations of excised portions of affected muscles have disclosed a condition of muscular hyperplasia. DEJERINE and SOTTAS (*Compt.-rend. hebdom. des Séances de la Soc. de Biol.*, No. 23, 1893, p. 669) make an interesting contribution to the subject of congenital myotonia, reporting the results of a careful post-mortem examination in the case of a man thirty-seven years old, who had been under observation for five years, and had presented characteristic symptoms from infancy, death occurring as the result of an attack of acute nephritis. The findings were entirely in accord with those of previous observations, but in addition careful examination failed to disclose a lesion of the central or of the peripheral nervous apparatus. The hyperplasia of the muscles was found to be due to changes in the primitive fibrillæ, and these were considered to be secondary to the increased functional activity, as they were not present in all of the muscles. Congenital myotonia will thus fall into the group of myopathies, together with pseudo-hypertrophic paralysis and its congeners.

EDITORIAL COMMENTS.

Cholera in Europe.—It is reported that cholera has appeared in Algeria—seventy or eighty cases—although the fact is denied by the official reports. At Marseilles, France, with from twelve to fifteen fatal cases daily, the British Consulate has ceased giving clean bills of health, and the French sanitary authorities have at last officially admitted the existence of sporadic cases. In the south of France generally the disease is spreading from town to town. A case of cholera has been reported in Piedmont, Italy, and several cases a day are reported from Naples, though denied by the authorities. In Arabia, Turkey in Asia, Russia, etc., the progress of the disease is slow but continuous. No new cases have occurred in England.

The Bad Physician and the Bad Musician.—There is something more than fancy, something more than sentiment, something even far more than analogy, hidden in

these facts: A good violinist, who knows and loves his instrument, will never allow a beginner or a bungler to play upon it. He knows that it will be all but spoiled in the hands of a bad player. By producing inharmonious vibrations in the wood the molecular structure is itself disturbed and confused. The longer, moreover, the attuning of the instrument by accurately harmonious vibrations, the more perfect the response of the wood, and the purer its tones. Just so it is with medicine, the therapeutic instrument, art, and artist. If we love medicine, we will not give the precious instrument to the bad and incapable, to damage irreparably its most intimate and ultimate structure.

The "Patent-medicine" Advertiser.—The American people should sell themselves body and soul to the nostrum-vender, or else combine to get some laws passed to curb his boundless greed and impudence. Go where one will, every barn, house, field, rock, or sign-board is turned into a blazing memento of our national disgrace, and of medical humbug. Pills, pills, pills! "The Gentleman's Friend," "Blood-regulators," "Pectorals," tonics, and heaven knows what else! Wherever the eye of child, girl, maid, man, or mother turns, there is the allusion, open or half-concealed, almost always filthy, to suggested disease. The images called up are those of pathologic conditions of the kidneys, of the genito-urinary organs, of the discharges from the bowels, of syphilis—of all the results of vicious, moral, or unphysiologic living. Is there no way to put a stop to such outrages against common decency?

Aluminum Drainage-Tubes.—*Apropos* of a brief comment in the NEWS of July 22, 1893, p. 107, an esteemed correspondent calls our attention to the fact that "aluminum drainage-tubes have been largely in use for several years. To my own knowledge for five or six years they have been made and kept in stock by the instrument-makers of Paris. They were first made by M. Collin, of that city, of three sizes of twenty centimeters in length, under the instructions of M. Lucas-Championnière, and are figured in the French catalogues of surgical instruments as 'Drains en aluminum du Championnière.'"

Purification of Water by Electricity.—It is reported that an "electric disinfectant" has been discovered by an electrician of New York, and, as a test, successfully applied to the purification of a large body of Croton water by Dr. Cyrus Edson. The details of the method are not given, but it is said that a powerful electric current passed through sea-water produces a fluid which has powerful antiseptic properties. This fluid in small quantities merely mixed with water containing nitrites, nitrates, and ammonium compounds, is said to dissipate these substances entirely.

The Word Practitioner.—We wish some professional etymologist would tell us the origin of the word *practitioner*, and publish the name of the lunatic who dared to coin such a barbarism. A man might be a practicer of medicine, but we do not understand how he could be a practitioner any more than one could be a musicianer or a mechanicianer. We have the words physician, doctor, etc.; why perpetuate the absurdity, practitioner? Let us drop it!

The New York Herald exposes another Bogus Medical College, passing under the name of "The Preparatory Medical College of New York." A certain Dr. W. M. Rew was the entire faculty and treasurer, and he sold a reporter a diploma for $20, after which he was arrested.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-sixth Annual Meeting, held at New London, Conn., July 18, 1893.

DR. GORHAM BACON, of New York, presided.

DR. LUCIEN HOWE, of Buffalo, N.Y., read the first paper, which was entitled "Note on the Comparative Anatomy of the Ossicles." Failing to find in various works on comparative anatomy adequate information in regard to the bonelets of the ear, an effort was made to obtain the ossicles from animals of widely different species. The view that the long process of the malleus is bony in early life, later degenerating into connective tissue and appearing as a ligament, seemed to be confirmed.

The view with regard to the malleo-incudal joint in the human being, that rotation in one direction is practically unlimited, while in the other direction it is suddenly arrested, was verified in the orang and some of the higher animals. It was found that the form of the hammer and anvil differs greatly, not only in different genera, but also in individuals of nearly allied families. On the other hand, the stapes is remarkable in having almost always a certain approach to the stirrup form.

DR. ALBERT H. BUCK, of New York, read a paper on the "Strongly Counter-irritant Effects of the Usual Mastoid Operation." It was pointed out that while the main object in opening into the mastoid process is the establishment of free drainage, in not a few cases the derivative and counter-irritant influence of the operation plays a most important part in effecting a cure.

In the majority of cases the disease will be cured without this additional counter-irritation, but in those cases in which the disease of the ear has set up more or less active intra-cranial inflammation, this counter-irritant power may be sufficient to turn the scale from a fatal to a favorable issue.

DR. HERMAN KNAPP, of New York, read a paper entitled "Extensive Caries and Necrosis of the Temporal Bone of a Child; Mastoid Operation; Death from Exhaustion and Hemorrhage."

The patient was a feeble, anemic child. For a few months there had been copious and offensive otorrhea of the left side. The mastoid region was swollen and soft, but no fluctuation was present. The mastoid was exposed, but there was no sub-periosteal collection of pus. The outer table of the mastoid was removed, exposing a large cavity filled with necrosed bone and granulations bathed in pus. This was removed and the cavity packed with corrosive-sublimate gauze. The child improved to some extent, but there was no tendency to repair. Some time later, and a week before death, the probe revealed that the

posterior wall of the bony portion of the external auditory canal had begun to loosen itself, but it was too firmly attached to permit of extraction. Careful probing of the ear was followed by the escape of dark blood. The wound was dressed and the child went home. During the night there was a continuance of the bleeding, and the child died on the following morning. It was impossible to obtain an autopsy. The amount of blood lost did not seem large enough to have caused death, but in the precarious condition of the child it may have hastened the fatal result.

Dr. Knapp further reported "A Case of Chronic Middle-ear Suppuration with Grave Brain and Lung Complications; Opening of Mastoid and Wounding of Lateral Sinus; Complete Recovery."

The patient was a woman, thirty-eight years old, who complained of pain, discharge and deafness in the left ear. For a year there had been occasional attacks of inflammation. The upper posterior part of the drum-membrane was red and bulging, and there was a large perforation in the lower part. There was also catarrhal rhinitis. Appropriate treatment was advised, and during the next three months the condition fluctuated considerably. On three occasions the condition became so aggravated that exploratory operation was decided on, but on each occasion sudden improvement occurred and operation was deferred. Finally, the disease took a more serious turn, with pain in the head and swelling and tenderness of the mastoid, and pain on percussion about two inches back of the ear. Operation on the mastoid was advised, but was delayed at the request of the patient on account of the advent of menstruation. The symptoms became more aggravated, although there was no discharge from the ear. When the mastoid was opened no pus or diseased bone was found. The bone was softer and more vascular the deeper the operation went. Chiselling still deeper, a sudden gush of dark blood took place, ceasing after a minute's pressure. The cavity was packed with corrosive-sublimate gauze. The ear showed no reaction, but for a week the patient was in a critical condition from a complicating pleuro-pneumonia. From the ninth day after the operation the patient improved steadily and made a complete recovery. It was thought that the attic disease was the origin of the difficulty, and that the inflammation extended into the skull through the roof of the drum-cavity.

Dr. J. Orne Green, of Boston, pointed out that the copious hemorrhage that sometimes takes place and is attributed to injury of the lateral sinus, may be due to the opening of a large diploic vein.

Dr. T. Y. Sutphen, of Newark, N. J., reported "Autopsies in Two Cases of Complicated Middle-ear Disease." The first case was in a man, thirty years old, with a history of long-continued middle-ear suppuration, who presented an immense abscess involving the left mastoid region, which was opened. During the next few days the patient became worse, with the development of cough, elevated temperature and dulness on percussion over the right side of the chest, and in a week he died in coma.

The autopsy disclosed an abscess-canal outside of the dura mater, extending to the cerebellum, where it penetrated the dura and led to an abscess in the brain-tissue, adjacent to which were other spots of softened tissue. There were also the lesions of a septic pleuro-pneumonia.

The second case was one of right middle-ear inflammation lasting several weeks. For ten days there had been severe headache on the right side, but no swelling or tenderness over the mastoid and no paralysis. Three days later the patient became comatose, with a temperature of 104°. On the following day the mastoid was opened, but no pus was found. The patient died the next morning.

The autopsy showed no communication between the mastoid and the cranial cavity, although the meningeal space contained a quantity of sero-purulent fluid. The right lateral sinus contained a large, softened clot, communicating with the meningeal cavity. The entire meningeal surface of the cerebellum was bathed in pus. No abscess was found in the brain-substance.

Dr. Emil Gruening, of New York, read a paper entitled "Fatal Thrombosis of the Lateral Sinus, with Autopsy." He reported the case of a woman, thirty-eight years old, who had had an occasional discharge from the left ear for six years, but for two months a profuse discharge. There were two perforations in the drum-membrane, and the mastoid region was red, swollen, and edematous. The ordinary mastoid operation was performed and pus and granulation-tissue found. The lateral sinus was exposed, but it did not pulsate. Four days later pyemic symptoms manifested themselves, with marked and sudden variations in temperature. There were also evidences of lobar pneumonia. The patient died, and the autopsy disclosed pneumonia and thrombosis of the lateral sinus.

Dr. Clarence J. Blake, of Boston, presented the statistics of the Aural Department of the Massachusetts Eye and Ear Infirmary for the three months, April, May, and June, 1893.

Dr. J. Orne Green, of Boston, exhibited a large number of pathologic specimens of ear-disease and gave reports of the cases.

Dr. Clarence J. Blake, of Boston, read a paper on "Stapedectomy and other Middle-ear Operations." As the result of an investigation conducted during the past year as to the feasibility and advisability of extracting the stapes in chronic non-suppurative disease of the middle ear, it was concluded that in those cases of non-suppurative disease of the middle ear, with a high degree of deafness, the operation of stapedectomy is most likely to be futile, because of the degree of fixation of the base of the stapes, leading to fracture of the crura in the attempts at removal.

In the class of cases in which stapedectomy has apparently given the best results, viz., fixation of the stapes as a sequence of chronic suppurative disease, it is by no means certain that equally good results could not have been obtained by surgical mobilization and subsequent care.

While removal of the stapes is by no means so hazardous a procedure, it still opens up the possibility of interference to an unknown degree with the most important part of the organ of hearing, and an almost equally important peripheral organ of equilibrium.

In order that the operator might, in the non-suppurative cases, avail himself of the coöperation of the patient and apply in the progress of the operation a series of

hearing-tests to determine the location of the principal obstacle to sound-transmission and determine the extent to which surgical interference was advisable, the plan of "exploratory tympanotomy" was devised.

Dr. Blake expressed a preference, when possible, in cases of non-suppurative disease of the middle ear, to begin with exploratory tympanotomy, which can be performed without general anesthesia, leaving it to be determined by the examination and tests made during the operation as to whether the stapes can or shall be removed or not. In suppurative cases it is preferable to first perform synechtomy, tenotomy, and crural circumcision with, if necessary, the additional application of an artificial drum, allowing a proper time-limit for the determination of the effectiveness of these procedures before submitting the patient to the final operation of stapedectomy.

Dr. Frederick L. Jack, of Boston, presented a communication entitled "Further Observations on Removal of the Stapes." He reported the employment of the procedure in thirty-two cases, in addition to the sixteen previously reported, with encouraging results. It was pointed out that the operation is followed by the best results in the class of cases in which, from the increase of tissue, the effects of suppuration or hypertrophic inflammation, the stapes offers an obstruction to sound-waves; by its removal the hearing is improved. The results in cases of otitis media chronica insidiosa, on account of failure to extract the foot-plate, are not encouraging. Inflammatory reaction is unusual, and is followed by no bad results. The hearing is not necessarily impaired by the subsequent growth of a thin cicatricial membrane over the fenestral niche. Some cases of tinnitus and aural vertigo are relieved, and there is little likelihood of causing permanent vertigo in cases in which this had not previously existed. It rarely happens that a patient improves for all tones. Improvement in hearing the human voice is out of proportion to the improvement for other sounds, and the reverse sometimes occurs. In some cases failure may be due to hemorrhage into the labyrinth at the time of the operation. This is believed to be a rare complication, but may have occurred in one or two cases. In removing the carious ossicles the stapes, if found diseased, should also be removed.

"Dr. C. H. Burnett, of Philadelphia, presented a paper on "The Surgical Treatment of So-called Ménière's Disease (Aural Vertigo)." He maintained that the name "Ménière's disease" is inaccurate and unjust —inaccurate because it is indiscriminately applied to all forms of aural vertigo, regardless of the seat of the otic lesion, whereas Ménière attempted to prove the existence of a disease of the semicircular canals as the only cause of aural vertigo, an entirely untenable hypothesis; and unjust because Flourens in 1822, and Deleau in 1836, described aural vertigo more accurately than Ménière in 1861, and Deleau came much nearer than any previous observer to the solution of the origin of aural vertigo in placing the cause in lesions of the middle ear.

Aural vertigo due to lesions in the middle ear is of frequent occurrence. It is often not recognized, especially by the general practitioner, as aural vertigo, nor even as the so-called Ménière's disease, in which, to say the least, the cause of the vertigo is placed in the auditory apparatus. It is not unusual for aural vertigo to be attributed to intestinal disturbance, or to "neurasthenia," instead of to an aural lesion. Hence, the diagnosis being erroneous at the outset, the treatment is wrong and the patients do not recover.

True aural vertigo, due to a lesion in the middle ear, chiefly from chronic catarrh of the tympanic cavity, is paroxysmal in character and attended with tinnitus and deafness in the affected ear. It is caused by the inward pressure exerted upon the labyrinthine fluid by the retracted and ankylosed ossicles. The foot-plate of the stapes is thus unduly pressed into the oval window, and there held by the forces named, paroxysmally and for longer or shorter periods.

The treatment consists in removing the retractive force and liberating the stapes, preferably by the surgical removal of the incus. The removal of the incus, which in its relation to the other two auditory ossicles, may be likened to a keystone in an arch, destroys the arch, and the retractive and impacting power of the malleus can never again be exerted upon the stapes. Thus the stapes is liberated and pulled outward by the stapedius muscle, relieved of the antagonism of the tensor tympani. The removal of the stapes from the oval window does not seem necessary for the relief of deafness or of aural vertigo. Liberation of the stapes and not its entire removal is all that is necessary in most cases.

Dr. Robert Barclay, of St. Louis, read a paper entitled "On the Difficulty of Operation in the Depths of the Ear-canal; with Description and Drawings of New Instruments for Surmounting it." He stated that the difficulties attendant upon deep operations within the ear are in large part due to the peculiar conformation of existent instruments— specula and shafts of blades. To obviate the objections belonging to the ordinary aural specula, Dr. Barclay has designed a new speculum, which consists of two parts, a tube and a handle. The tube represents the inner portion of the ordinary speculum, divided obliquely at two-fifths its distance from the outer rim. The handle is detachable and is made in three forms: like a spoon-handle, fixed to the tube dipper-shaped; like an imperfect ring, or like a split tailor's-thimble. By means of the handle, the instrument is held in place by the finger or thumb, the rest of the hand being free. By dispensing with that portion of the speculum that projects beyond the intertragal notch of the ear, this instrument allows a hand-rest for steadiness, and a maximum of shortening and of movement of instruments in operations within the ear.

Dr. Barclay has also devised a shaft and handle so proportioned as to combine the desirable features of those already in use, without their defects. The essential features of the instrument are that the aluminum handle is of dimensions and weight most favorable to delicate and accurate manipulation; it is twice bent, the long axis of the handle passing directly through the operative extremity of the operating shaft. The lateral shaft joining the handle to the operating shaft is of length only sufficient to permit the greatest illumination and vision along and beyond the operating shaft. The operating shaft is of of the smallest dimensions possible and is at right angles to the lateral shaft. The instrument is made in two

forms. In one the handle and shaft are in one piece. In the other, the instrument is in two parts and separable, and interchangeable blades of such extremities as may be desired may be secured to the handle.

Dr. Samuel Theobald, of Baltimore, read a paper entitled "Aural Reflex of Unusual Character Due to Impacted Cerumen." A woman, about forty-two years old, the mother of a large family, and not of a nervous temperament, had suffered for six months with an annoying cough and with attacks of inability to swallow food. These symptoms increased in severity, and it was noticed that any manipulation of the right ear brought on an attack. A plug of cerumen, which probably had been forced down upon the tympanic membrane by unsuccessful attempts to remove it, was discovered in the right ear. It was removed by syringing and all the unpleasant symptoms at once disappeared.

Dr. B. Alex. Randall, of Philadelphia, read a paper on "The Statistics of Ear-Disease."

Dr. Gorham Bacon, of New York, exhibited a new form of incus-hook, devised by his assistant, Dr. Hewit.

A paper entitled "A Contribution to the Brain-surgery of Ear-Disease," by Dr. Thomas R. Pooley, of New York, was read by title.

The following gentlemen were elected to membership: Dr. Edward B. Dench, of New York; Dr. William Cowen, of New York; Dr. John L. Adams, of New York; Dr. Edward Fridenberg, of New York; Dr. W. H. Wilmer, of Washington, D. C.

The officers elected for the ensuing year are: President, Dr. Gorham Bacon, of New York; Vice-President, Dr. Arthur Mathewson, of New York; Secretary and Treasurer, Dr. J. J. B. Vermyne, of New Bedford, Mass.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-ninth Annual Meeting, held July 19 and 20, 1893, at New London, Conn.

Dr. George C. Harlan, of Philadelphia, presided.

Dr. Charles A. Oliver, of Philadelphia, read a paper entitled "The Relation of the Patellar Tendon-reflex to some of the Ocular Reflexes found in General Paralysis of the Insane."

In some of the cases in the second stage of the disease, especially when the patellar tendon-reflexes were unequally exaggerated, there appeared to be an irregular and unequal spastic contraction of the two irides, causing irregularities in pin-point pupil-forms. In a few cases, especially in the third stage, in which the patellar tendon-reflexes were unequally diminished, the pupil-size, though small, and its shape, though somewhat irregular, seemed to be but little acted upon by any powerful mydriatic.

In many cases, especially in comparatively young subjects in the third stage, in which the patellar tendon-reflexes were unequally diminished, there appeared to be an unequal paralytic condition of the two irides; the pupillary dilatation manifesting itself at times, though not as a rule, in the eye with the greater amount of objective optic-nerve degeneration and retinal change.

In a few cases (especially in men beyond middle life) in the third stage in which the patellar reflexes were markedly diminished and ataxia was quite pronounced, there were marked temporary asymmetries of pupillary form, one often being quite small and irregular for several examinations, while its fellow was large and ovoid or oval.

In quite a number of cases, especially in the advanced stages of the disease (although seen in a number of cases in their earliest stages) in which the patellar tendon-reflexes were unequally exaggerated or diminished, there was a failure of the irides to respond to even major degrees of light-stimulus; this being true not only for those subjects exhibiting a true spastic myosis, but more especially in those instances in which, with partial dilatation of the pupil, mydriatics failed to act.

In many instances, especially in the older cases in which the patellar tendon-reflexes were, as a rule, unequally diminished or even lost, there was not only failure of iris-response to the strongest light-stimulus carefully thrown upon the retina, but when obtainable the irides seemed to fail to react to the various coarse and rough subjective and objective procedures necessary to evolve both separated and associated efforts for accommodation and associated efforts for convergence.

In some instances in which ciliary muscle innervation could be satisfactorily obtained, both the spastic excitation and the paralytic condition, at times found by subjective reading-tests and objective study with the retinoscope, seemed to be in direct ratio with the patellar tendon-reflexes and the iridic changes.

In quite a number of cases in which there was marked inequality of the pupils, with more or less want of reaction of the irides to light-stimulus, the patellar tendon-reflex on the side of the larger pupil seemed to be the more greatly diminished. In a number of instances, especially during the very earlist stages of the disease, when the patellar tendon-reflexes were beginning to lessen to unequal degrees, there often appeared momentary secondary ataxic dilatation of the pupil during exposure to strong light-stimulation.

In many cases, especially during the second stage, when the patellar tendon-reflexes began to become irregular and inconstant, pupillary inequalities, as expressive of unequal iris-innervation and action, became more and more constant.

Dr. Oliver also presented the "Clinical History of a Case of Spindle-celled Sarcoma of the Choroid, with a Study of the Microscopic Condition of the Growth."

The patient was a man, thirty-four years old, who five years before had suddenly noticed that objects situated to the right became dimmed when he attempted to look at them with the left eye. This condition gradually involved the whole field of vision, until in a little more than three years the eye became blind.

A tumor of the choroid was discovered after two years. There was a history of syphilis, but specific treatment had no effect upon the growth, and a diagnosis of sarcoma was made, and operation urged but not accepted. The growth attained a large size and became quite vascular. The eyeball was finally removed, perfect recovery ensuing. Microscopic examination showed the growth to be a spindle-celled sarcoma.

Dr. Emil Gruening, of New York, read a paper on "Sarcoma of the Choroid." He reported the case of a woman, thirty years old, who, with impairment of sight in the right eye, presented a pushing forward of the

retina in the mascular region. Sarcoma was diagnosticated and the eye was removed. Examination showed the growth to be a spindle-celled sarcoma.

DR. GRUENING also read a paper on "Sarcoma of the Eyelid." He reported the case of a man, twenty-three years old, who for five years presented a swelling upon the lower lid of the right eye, which bled freely and irregularly. It was operated on, but soon recurred. The skin covering the mass was freely movable. A small portion was removed and found to be sarcomatous. The tumor, with the entire thickness of the lid, was then removed and the lid restored by a plastic operation.

DR. H. KNAPP reported two cases of traumatic sarcoma of the lid, both terminating fatally.

DR. GEORGE C. HARLAN, of Philadelphia, read a paper entitled "Tumor of the Iris, probably Tuberculous." He reported the case of a male child that, at the age of two and a half years, presented defective vision upon the right side, with photophobia and lachrymation. There was some conjunctivitis, but no chemosis. There was a small posterior synechia. A number of small, yellowish-white, rounded nodules were visible at the periphery of the iris. These increased rapidly in size, and additional ones formed. The deposit increased rapidly, and soon filled the upper outer third of the anterior chamber, and completely covered the pupil. Intense photophobia of the sound eye developed, and the diseased eye was enucleated. After the operation the condition of the child rapidly improved. Microscopic examination indicated that the lesion was probably tuberculous, although bacteriologic examinations yielded negative results.

DR. B. ALEXANDER RANDALL, of Philadelphia, read a paper entitled "Reflections upon a Disastrous Case of Ophthalmia Neonatorum." He pointed out that occasionally the most careful precautions may fail to prevent the disease or bring it to a successful termination. He referred to a case in which he could find no fault with the prophylactic or the therapeutic measures, yet both eyes were lost, and protested against too uncompromising claims as to the powers of medical measures, as such claims may be two-edged weapons that may be turned most seriously against their authors or other medical men who have really done all that human means could effect.

DR. B. L. MILLIKEN, of Cleveland, Ohio, detailed some "Clinical Notes on Some Refractive and Muscular Cases." Six cases were cited in which attempts were made to correct high degrees of astigmatism by the ordinary means, but without satisfactory results, while the ophthalmoscope furnished most excellent corrections.

Several cases were reported showing what could be accomplished with prisms in the correction of muscular insufficiencies, and the question was raised as to the advisability of wearing prisms at various angles for the purpose of correcting both a lateral and a vertical muscular insufficiency with the same glass. For instance, in a case of a lateral insufficiency of, say, ten, and a vertical insufficiency of ten, instead of making two prisms to correct, one at 90° and the other at 180°, place a 2° prism at 45° or 135°, right or left, as the case might be. The histories of several cases of this kind were given in which patients had worn the glasses thus with much benefit.

DR. SAMUEL THEOBALD, of Baltimore, reported "Several Cases in Which the Vertical Diplopia Test Proved Untrustworthy." Four cases were reported in which the cover-test showed a high grade of exophoria, both in distant and in near vision, but in which the vertical diplopia test failed entirely to demonstrate the presence of the condition, in some of the cases even indicating esophoria. In one of these cases, and also in a case of esophoria, it was found that when, during the application of the vertical diplopia test, the cover-test also was employed, a squint would show itself in the excluded eye, which the vertical prism failed to bring out, and which would disappear upon the removal of the cover, though the vertical diplopia was still maintained, showing that the latter had no controlling influence over the action of the lateral muscles. Cases in which the vertical diplopia test proves untrustworthy are comparatively rare.

DR. SAMUEL THEOBALD, of Baltimore, read a paper entitled "An Additional Note in Reference to the Case of Useful Vision Maintained by Means of a Totally Dislocated Lens," heretofore reported to the Society.

The feature of interest was that a fragment of the dislocated lens, the capsule of which had ruptured two years before, fell through the pupil into the anterior chamber, where it remained for six months, resisting the solvent and opacifying action of the fluids of the eye so completely as to retain its transparency and its sharply cut angles. It closely resembled a bit of yellowish glass, and might easily have been mistaken for a foreign body. As its presence in the anterior chamber began to cause considerable irritation, the pupil was dilated and it was caused to fall again into the vitreous chamber, its return to the anterior chamber being prevented by the employment of a myotic. This was followed by the disappearance of the irritation, which has not since returned. The insolubility of the lens-fragment is the more remarkable in view of the fact that the patient was but twenty-two years old at the time the lens-capsule ruptured.

DR. CHAS. A. OLIVER, of Philadelphia, presented a series of wools for the ready detection of "color-blindness." The following modifications had been made in the Holmgren series:

Five individual tests are employed—pure green, pure red, rose, pure blue, and pure yellow. Loose und separate skeins of wool are employed. The colors are made of equal relative intensity. The value of the color used in each test skein is definitely expressed. The set is so constructed as to be used by any intelligent layman; so that passing color-changes can be preserved and permanently kept for future comparison; and so that written and verbal expressions of the character and the amount of the subnormal color-perception can be given.

The wools are made of one grade of manufacture, and dyed with vegetable material.

After several years' trial it has been found that all but the five principal test skeins, five pure match skeins, and eighteen confusion skeins of relative equal value to the pure match skeins can be dispensed with.

DR. CHARLES STEDMAN BULL, of New York, read a paper on "Gouty Retinitis, Choro-retinitis, and Neuro-retinitis," based upon a study of the retinal changes found in over one hundred gouty patients. It was pointed out that the changes in the fundus are always

bilateral, though rarely symmetrical in the two eyes. The degeneration in the walls of the bloodvessels and in the retina cause marked impairment of central vision, little or no impairment of peripheral vision, and never end in blindness. The loss of central vision is always progressive up to a certain point, unless the cause of the disease is recognized early and immediately and properly handled. Improvement of vision after the disease is established cannot be expected. Hemorrhages into the retina are rare, except in the beginning of the disease. Their absence later is probably due to the fact that the strength of the vascular wall is increased by the deposit, though its elasticity is diminished. The most marked feature in the fundus is the development of the arterio-sclerosis and the phlebo-sclerosis. This is seen by the ophthalmoscope in the vessels of the retina, and the microscope shows that the degeneration exists as well in the vessels of the choroid and optic nerve.

Another almost equally pathognomonic symptom is the peculiar yellowish granular exudation in the retina, located by the ophthalmoscope around the posterior pole of the eye, and generally leaving the macula intact, and proved by the microscope to be mainly in the nerve-fiber layer, though found in all of the layers except that of the rods and cones. The changes in the optic-nerve fibers seem to be almost entirely intra-ocular, and cannot be traced for any great distance back of the eyeball.

Dr. Myles Standish, of Boston, read a paper on "Retinitis Punctata Albescens." It was stated that the majority of cases present themselves on account of some discomfort in the use of the eyes, and in the course of the examination the white, rounded, glistening spots are discovered in the retina. After a time the eye can again be used with comfort, but the spots do not disappear. The nature of the substance deposited is not known.

Dr. Lucien Howe, of Buffalo, presented a communication entitled "Removal of Hard Cataract by Suction." In order to obviate the difficulty occasionally experienced in completing the final act of extracting the lens, an instrument similar to a large dropping-tube is applied to the protruding lens, creating a partial vacuum, and thus exercising traction.

Dr. Frank W. Ring, of New York, exhibited an ocular mask of papier-maché, to be used for the protection of the eye after cataract-operations.

Dr. Edward Jackson, of Philadelphia, read a paper on "The Artificial Ripening of Cataract." He reported a series of cases treated by tapping the anterior chamber, drawing off the aqueous humor, and massage of the lens through the cornea.

The operation was followed by very little reaction, there being no iritis or posterior synechiæ in any case. In patients over fifty years of age the operation was followed by rapid increase in the opacity of the lens and early maturity of the cataract. In patients under thirty-five years of age no effect upon the existing lens opacity was produced.

It was concluded that this method of ripening cataract is more efficient than that of Foerster (iridectomy and massage); that it is almost entirely free from danger; that it is probably a better means of avoiding prolonged practical blindness than the extraction of the immature cataract.

Dr. Herman Knapp, of New York, reported "A Case of Traumatic Dislocation of the Iris Under the Unbroken Conjunctiva; the Eye Damaged but Preserved; Typical Sympathetic Ophthalmia in the Other Eye."

A male, forty-five years old, was struck upon the left eye by the head of a small pet dog with which he was playing. The eye became discolored, but not painful. On the inner side of the cornea, and 2 mm. from its margin, the conjunctiva was raised by a black mass, which proved to be the iris. The conjunctiva showed no wound or scar. The whole iris was found absent from its normal position. The lens was in place and transparent. There was no neuro-retinitis or isolated rupture of the choroid. Vision equalled 15/200. The right eye was free from any irritation. The patient was directed to bandage the injured eye lightly, and not to use the other eye, and to keep quiet. Everything did well until twenty-nine days after the accident, when symptoms of sympathetic inflammation appeared in the right eye. Under active treatment the attack subsided, but relapses occurred, and vision in the right eye was completely lost. In the left eye vision equals 2/200, and the displaced iris has shrunken to a flat blackish mass, scarcely raised above the conjunctiva.

Dr. E. E. Holt, of Portland, Me., read a paper entitled "Removal of Steel from the Vitreous with the Electro-magnet." He reported three cases in addition to six previously reported. In all, the piece of steel had entered through the anterior chamber, fracturing the lens. The conjunctiva was separated and an incision made through the sclerotic behind the equator of the eye, the knife in each instance striking the foreign body. The electro-magnet was then introduced and the steel removed. The lens was subsequently absorbed and good vision obtained in every case, notwithstanding the fact that in the third case there was pus in the anterior chamber when the case came under observation.

A permanent magnet for use in removing foreign bodies from the cornea was described by Dr. Walter B. Johnson, of Paterson, N. J. It consists of a bar of steel, cone-pointed and elongated at each end. It is charged by rotating it within the magnetic field of a generator. It will continue in full magnetic strength for a long time. It has served an excellent purpose on several occasions in removing small particles of steel from the cornea which had perforated and almost entered the anterior chamber.

Dr. Walter B. Johnson, of Paterson, N. J., read a paper entitled "Suppression of the Visual Image." He reported the case of a man, nineteen years old, who had been cross-eyed since the age of three years, and has never been able to discern any object with the left eye. The right eye was hypermetropic. With the left eye fingers could be seen at six inches. As the result of an accident, enucleation of the right eye became necessary. In a few days fingers could be seen with the left eye at a distance of three feet; examination showed a hypermetropia of 1.50 D. With careful practice and instruction vision rapidly improved, in two weeks reaching 20/15 with a correcting glass and Jaeger No. 1 at twelve inches. Examination three years after the loss of the eye showed that the improvement had continued.

Dr. George C. Harlan, of Philadelphia, reported a "Case of Congenital Cyst of the Orbit with Anophthalmus

in a Well-developed and Healthy Child Five Months Old." The left eye and appendages were perfectly normal. A tumor about the size of a small hen's egg filled the right orbit and projected considerably beyond it. The orbit was as large as an adult's, and the lids were distended to more than twice their normal size. The skin was movable and of natural appearance. The cilia were well developed. The lids were separated about 2 cm. The exposed conjunctiva was congested, but otherwise not much changed. There was no discharge. There was nothing to mark the position of the cornea. There was no movement and no pulsation in the tumor, which was incompressible.

As the tumor was growing and the deformity great, removal was decided upon. Incision through the conjunctiva gave exit to a quantity of clear, watery fluid. The cyst was simple, the outer portion being fibrous and tough and the inner delicate, semi-transparent, and bluish.

The child died twenty-four hours after the operation, apparently from exhaustion following upon shock.

A careful inspection of the orbit after death showed that there was no communication with the intra-cranial cavity. Nothing resembling an eye could be found in the extirpated cyst, though at the bottom of the sac there was an undefined mass of tissue.

The tumor was thought to represent the embryonic tissues of the eye, in a condition of exaggerated hydrophthalmus, or a fetal encysted coloboma, which by its early inception and enormous growth had prevented the evolution of the eye.

Dr. Samuel B. St. John, of Hartford, Conn., read a paper entitled "Restoration of the Upper Eyelid by Means of a Flap taken from the Cheek." He demonstrated a method applicable to cases in which the upper lid had been destroyed by disease or injury, or had been removed by operation. In making the flap, the incision commences about half an inch in front of the ear and runs forward below the lower lid about half an inch and continues until the side of the nose is reached. It is then carried downward until the flap is of sufficient width, then taken backward. The flap is next separated and secured by numerous stitches to the freshened surface above. The gap left is closed by separating the tissues of the cheek below the wound and sliding them upward.

Two cases were reported in which this plan had been employed with success.

The following were elected to membership:

Dr. F. E. Cheney, of Boston; Dr. J. E. Weeks, of New York; Dr. Charles H. Thomas, of Philadelphia; Dr. George Fiske, of Chicago; Dr. Wm. H. Wilmer, of Washington, D. C.; Dr. Edward Fridenberg, of New York; Dr. H. B. Chandler, of Boston; Dr. Wm. Cheatham, of Louisville.

The following were elected the officers for the ensuing year:

President, Dr. George C. Harlan, of Philadelphia; Vice-President, Dr. O. F. Wadsworth, of Boston; Secretary and Treasurer, Dr. Samuel B. St. John, of Hartford; Corresponding Secretary, Dr. J. S. Prout, of Brooklyn.

The Society adopted a by-law limiting the membership to one hundred and fifty.

NEWS ITEMS.

The State Medical Examining Board of Washington held its regular semi-annual meeting in Spokane, July 5, 1893. Thirty-one candidates were present and certificates were granted to eighteen, thirteen failing to obtain the required percentages. The Board decided to discontinue the practice of granting temporary licenses. This was considered necessary, as, in certain cases, unscrupulous persons obtained them and palmed them off as licenses issued after examination. The medical societies generally throughout the State also petitioned for their revocation. Hereafter a total average of 75 per cent. will be required of candidates. The next meeting will be held in Seattle the first Tuesday in January, 1894.

Section on Materia Medica and Pharmacology, Pan-American Medical Congress.—A Section on Materia Medica and Pharmacology has been organized under the Executive Presidency of Professor Joseph P. Remington, of Longport, N. J., with Professor F. G. Ryan, of Philadelphia, as English-speaking Secretary. This Section promises to be an important one. Delegates have been invited from all the pharmaceutic societies and colleges in all the Americas. Those contemplating attendance are invited to prepare papers on pharmaceutic topics, the titles of which should be sent at once to Professor Ryan.

Dr. J. Moore Campbell, a physician in active practice in the southern part of this city, died July 14, 1893, of enteric fever, in the forty-fourth year of his age. He was graduated from Jefferson Medical College in 1878, and was for several years chief clinical assistant in the department of gynecology of the College Hospital. Appropriate resolutions have been adopted by his graduating class organization.

The Vermont State Medical Society will hold its eightieth annual meeting at Rutland, October 12 and 13, 1893. Two prizes are offered for the first and second best papers on either "Peritonitis" or "Septicemia."

Pettenkoffer, of Munich, the distinguished hygienist, celebrated, on June 30th, the fiftieth anniversary of his graduation in medicine.

SYMPHYSEOTOMY[1] IN NORTH AND SOUTH AMERICA, WITH REMARKS UPON ITS GROWTH IN EUROPE.

BY ROBERT P. HARRIS, A.M., M.D.,
OF PHILADELPHIA.

FOR 115 years after the introduction of Sigault's operation, in 1777, no one ever ventured to perform it in our Western Hemisphere; and it was not until the evidences in its favor were startling and beyond dispute that the initial step was taken, in Brooklyn, on September 30, 1892, by Professor Charles Jewett. This trial was quickly followed by others, and 4 operations were performed in the following month in the United States. In November the operation was performed in Rio Janeiro, Brazil; and in December, in Montreal, Canada. In the United States, Brazil, and Canada, 29 women have been operated upon in 9 months, divided as follows: In the United States, 25; Brazil, 2; and Canada, 2. In our own country the cases have been distributed as follows: In Philadelphia, 8; New York, 7; Brooklyn, 2; Cincinnati, 2; and 1 each in Baltimore; Paris, Illinois; Springfield, Illinois; Pittsburg; Portland, Oregon; and Boston. Rio Janeiro has a credit of 2 cases, and Montreal, Canada, has the same, all of the women and children having been saved. Dr. Anna E. Broomall, of Philadelphia, has operated upon 3 women; Dr. Barton Cooke Hirst, of the same city, upon 2; Dr. Egbert H. Grandin, of New York, upon 2; and Dr. Rodriguez dos Santos, of Rio Janeiro, upon 2.

Four women of the 25 operated upon in the United States have died, and 6 children have been lost, 3 of the latter having been still-born. Twenty-two children were born alive. Three of these died: 1 in 24 hours, from long head-pressure; 1 on the third day from meningeal hemorrhage; and 1 in 17 hours from injuries received in attempts to deliver.

Cases IX, XIII, XV, and XXIV, died. Case IX was in labor 25 hours, had a pulse of 150 when operated upon, and died of exhaustion in 17 hours. Case XIII died after 12 days, of septic peritonitis, believed to have been entirely puerperal. Case XV died in 72 hours of double pneumonia, which was believed to have arisen from exposure in riding to the Maternity on a cold, rainy day. Case XXIV died on the eleventh day from sepsis, having its origin in the symphysis. The woman was a 12-para, and was three days in labor before going to the hospital. The case closely resembled the twentieth of Dr. Pinard, of Paris, which was the first in his hands to prove fatal.

The Brazilian symphyseotomies were the work of one well known as an obstetric writer in South America. One operation was performed upon November 11, 1892, and the other on February 13, 1893. The subjects were young Brazilian primiparæ, aged respectively nineteen and twenty-one years, who had contracted pelves, but to what extent the letter of the operator to me does not state. In each case the vertex presented, and delivery was accomplished by the forceps, the child being a male. The mothers made good recoveries, had no subsequent disabilities, and they with their sons were alive and well on June 15, 1893, when Dr. dos Santos wrote, one child being then seven, and the other four months old.

Symphyseotomy may be said to have had three periods in its existence: (1) from 1777 to 1858 inclusive, after which there was no operation during seven years; (2) from 1865 to 1886; and (3) from 1886 to the present time. What most concerns us is the third period, in which the technique of the operation has been perfected; the number of operations vastly increased; and the mortality, under antiseptic management, largely diminished. As an evidence of its spread and of the growing confidence in which it is held, it is only necessary to state that there were twelve operations in Naples in 1891, and none in any other locality; that in 1892 there were more operations in Paris than in Naples; and that the average per month in all countries collectively, during the past eighteen months, has been more than twelve. Judging from the records of the first six months of the current year I am led to believe that there may be as many as two hundred women operated upon throughout the year; or more than will be delivered by the Conservative and Porro-Cesarean sections together. The Porro-Cesarean operation has been adopted by twenty-one countries in a period of sixteen years; while, already, that of pubic section, in a year and and a half, has been tested in eleven countries. This sudden advance into popularity has been thought a *wild* one by many careful men, and there

[1] This mode of spelling is in deference to the wishes of Dr. Harris.

will, no doubt, be a reaction in time; but the method has a certain degree of merit, and the true measurement of it, as well as its legitimate death-rate, will in time be ascertained. Its mortality, except in Naples, has been much too high since January, 1892, and the proportion of children lost will make many obstetric surgeons cautious about adopting it in given cases. The death-rate at the present time is fully 12 per cent. for the women, and from 18 to 20 per cent. for the children. It has, besides, the serious objection that many primiparæ delivered through its intermediation by the forceps have extensive lacerations of the vagina, vulva, and perineum, to be repaired. At one time, about three out of four women (1866–1885) were allowed to deliver themselves; but since January, 1886, a large majority of children have been extracted by the forceps or by version. The infantile mortality under both methods has been about the same, as nine were lost out of fifty, when only about one out of four was forcibly delivered, or 18 per cent. There were, however, at the same period, ten women lost out of fifty, instead of 6, as the present rate reads.

Compared with the Conservative Cesarean operations of the best European maternities, we find that symphyseotomy has a greater mortality, both for mothers and children, and the difference is very marked as to the latter. If a hundred Cesarean operations are performed in good season, and particularly if entered upon a few days before the period of gestation has been completed, there should be a hundred children delivered fully alive, if in this condition when the celiotomy is commenced, except in the cases in which the Esmarch elastic tube has been applied around the cervix, when asphyxia of the fetus may be looked for. Under the Porro-Cesarean operation, the fetal loss has been twenty-one per cent. in 443 delivered, and the deaths in 1890 reached one-fourth, and in 1891, one-third, *due mainly to delay* and to the class of cases chosen to be operated on; although in these two years, eighty-one women were saved out of ninety-five. The women lost were fourteen, against twenty-eight children.

So far, then, as the children are concerned, the highest mortality has been under the Porro Cesarean section; the second, under antiseptic symphyseotomy; and the lowest, under the Conservative Cesarean operation as performed in Leipzig, Dresden, and Vienna. That the Porro cases may also be so managed as to have but little fetal loss, is shown by the records of the Krankenhaus, of Vienna, and some of the noted Maternities of Germany, where cases are rarely operated upon *in extremis*.

Symphyseotomy, to be performed in the interest of the fetus, ought not to be selected when the pelvis has a *very* short conjugate, as the head may prove to be too large in proportion to admit of a safe delivery. There is a temptation to combine induced labor, symphyseotomy, and version in cases in which the conjugata vera is below two and three-fourths inches, and some children have done exceptionally well under this management; but it is to be remembered that premature infants are difficult to raise, and that rhachitic mothers, as a rule, are neither wise nor wealthy. It is safer to direct our obstetricians not to be too venturesome, and to remember that, as a rule, the fetus in our country is nearly a pound heavier on the average than the fetus in Europe, where the minimum conjugate has been put down at sixty-seven millimeters (two and five-eighths inches). In one woman operated upon in this city the conjugata vera was exactly two and three-fourths inches; but the fetus, being a male weighing eight pounds two ounces, made a very narrow escape from death by asphyxia. Neither should this method of delivery be selected in a case such as presented itself recently in Philadelphia, in which a rhachitic woman was in labor two or three weeks before maturity, and in which the funis could be felt through the membranes in advance of the head. The anxiety of the parents for a living child here settled the question in favor of the Cesarean section, by means of which the fetus, whose pulse was also indicative of an extra risk, was saved. Having seen this rhachitic dwarf in her labor, I can testify to the interest felt in the question at issue, as the conjugata vera was two and three-fourths inches, and the fetus was believed to be small, which it proved to be.

It is a mistake to attempt to substitute symphyseotomy for the Cesarean section, on the ground that the former is the less dangerous to the woman. We must distinguish between the relative possibilities of the two operations, and their general results. The Cesarean operations of Leipzig, Dresden, Vienna, and Glasgow (under Cameron), as far as they have come to me, show that it is possible to save one hundred and thirty-two out of one hundred and forty-two women, giving a mortality of 7 per cent. Prof. Adolphe Pinard, of Paris, saved nineteen out of twenty women upon whom he had performed symphyseotomy. Italy, since January, 1886, has lost two women and five children under forty-six symphyseotomies; but no other country has been able to save anything like this proportion. Years of experience and misfortune have enabled her to do this, and to set such a hopeful example for imitation. But we must base our hopes of success upon much lower figures, and, upon a general record, which in the last seven and one-half years, in eleven countries, including Italy, gives, out of two hundred

and five cases, twenty-five maternal and thirty-seven infantile deaths.

The subosseous operation of Naples, which originated in Spain in 1780, and was reintroduced many years later by Galbiati, of Naples, is the one which has usually been performed in this country; cutting from within outward, and from below upward, in preference to the direct incision of Sigault, as still practised by Pinard and others of France. The knife of Galbiati has been remodelled, and now presents a longer body to the blade, and a shorter curved extremity, the whole edge being made to conform to the postero-inferior curve of the symphysis, as it is found in the majority of deformed pelves. Should this joint be three inches deep, instead of an inch and a half, as it is sometimes fonnd, the operator will be obliged to suit his instruments to the case. We believe that in this country it is better to preserve the tissues in front of the symphysis; and that we should aim to avoid the bloodvessels behind and in front of it, knowing that wounding them may lead to death by sepsis, as has happened in Paris and in Philadelphia. As Naples, and not Paris, has been the great center of success, we prefer to follow what Morisani teaches, after an abundant experience covering twenty-seven years. France has much to learn yet; as, since the revival of the operation, five women and thirteen children have been lost as a result of the first thirty-five pubic sections directly made; and this record includes the first eight successes of Pinard.

RENAL NEOPLASMS, WITH REPORT OF TWO CASES OF NEPHRECTOMY.[1]

By WILLIAM MACKIE, A.M., M.D.,
SURGEON, MILWAUKEE HOSPITAL, MILWAUKEE, WIS.

Neoplasms, as they occur in the kidney, have been classified either histogenetically or histologically. Paul[1] adopts the former method, and divides them into those of congenital and adult origin. Those of congenital origin include sarcomata and dermoid tumors, and those of adult origin, cysts, sarcomata, adenomata, and carcinomata. In proof that sarcoma is of congenital origin he cites the case of a seven months' fetus in which the kidneys weighed twelve ounces, and the medullary portion of each was made up of nodules of a white new-growth, and the cortex was mottled with the same, yet there remained from twenty to thirty times the normal amount of renal tissue. These nodules consisted mostly of round cells, but in many parts they arranged themselves as though attempting some higher evolution. This he prefers to call a round-celled sarcoma. He also refers to another case of an eight months' fetus, described by Osler as one of adeno-sarcoma, and confirmed by himself. Cohnheim classes the sarcomata in children amongst the teratomata, and so does Dohrn.[2] Histologically, the new growths are divided into benign and malignant, and the following is the classification given by Newman:

A. Benign: 1. Fibromata. 2. Lipomata. 3. Hematangiomata. 4. Adenomata. 5. Papillomata.

B. Malignant: 1. Carcinomata. 2. Lympho-adenomata. 3. Sarcomata.

A. Benign.—

1. *Fibromata.* These are of comparatively rare occurrence. Out of seventy-four nephrectomies tabulated by Newman, five were for fibromata. These tumors sometimes reach a great size. Thomas removed one originating from the capsule of the kidney weighing ten and a half pounds; and Bruntzel, one weighing twenty-seven and a half pounds. Both patients made a good recovery. These were simple fibromata. Billroth removed a fibro-myoma, weighing forty pounds, with a fatal result. Fibro-cystoma and fibro-lipoma have also been met with.

2. *Lipomata.* These are still more rare than the foregoing. Ebstein records a case in which one kidney consisted wholly of lipomatous tissue. Spencer Wells[3] removed two fibro-lipomata, one from either kidney, weighing sixteen and a half pounds and fourteen and a half pounds, respectively. With that originating from the left kidney was removed one calix and papilla. Mr. Eve, in preparing the specimens, gave it as his opinion that their origin was from the circumrenal connective tissue; hence these cannot be regarded as true tumors of the kidney.

3. *Hematangiomata.* These occur as small nodules situated in the cortex and usually do not exceed in size that of a bean, and do not call for operative interference.

4. *Adenomata.* These occur in two forms, the papillary and alveolar: the former originate in the medulla and consist of tubules and acini into which the papillæ project, and are lined with cylindrical epithelium; the latter originate in the cortex, and are formed of dilated tubules lined with epithelium similar to that found in the convoluted tubes. They rarely attain any great size. Czerny operated upon a child of eleven months, with a fatal result; Schönborn successfully in a child of two years; Albert, in a woman of forty-one, and the tumor was as large as a child's head; Weir,[4] in a man of thirty-five, the kidney weighing twenty-one ounces; and Keyes,[5] in a gentleman of forty-nine. In the last case almost all traces of normal renal tissue were destroyed and the kidney appeared to be composed of an enormous number of nodules separated by newly-formed connective tissue. In Weir's case the new-growth was separated from true renal tissue by a dis-

[1] Read before Wisconsin State Medical Society, May 4, 1893.

tinct capsule. Walter Edmunds[6] reported to the Pathological Society of London a similar case, in which a globular tumor, two and one-half inches in diameter, projected from the anterior surface of the kidney, and extended internally into one of the calices. It consisted of cysts of various sizes, lined by cubical and columnar epithelium, and was enclosed in a distinct capsule. The kidney-tissue was healthy. Edmunds agrees with Shattuck in the belief that such growths are due to inclusion of remnants of the Wolffian body, because of the existence of a distinct limiting capsule.

5. *Papillomata.* These grow from the mucous membrane of the pelvis, are identical in structure with those found in the bladder, and the principal symptom present is hematuria. Jones[7] records the case of a patient who, while walking, was suddenly seized with faintness and an urgent desire to urinate. The fluid evacuated consisted of almost pure blood. Eighteen months after the first attack the kidney was explored, and a papilloma was found in the pelvis, and was removed. The hematuria recurred in four months, and eight months after the first operation nephrectomy was performed, and a papilloma, the size of a hen's egg, was found occupying the pelvis. Papillomata rarely give rise to any appreciable renal enlargement unless hydronephrosis is produced by a blocking of the ureter. Knowsley Thornton[8] met with such a case in a woman thirty-two years of age, who for twenty-nine years had suffered from discomfort and pain in the right renal region. On removal by abdominal nephrectomy he found a hydronephrotic kidney containing two pints of cloudy urine, several calculi, and the ureter blocked by a papilloma.

B. Malignant.—Primary malignant growths of the kidney are unilateral and form tumors of considerable size; the secondary are bilateral and do not give rise to any considerable enlargement of the organ.

1. *Carcinomata.* The medullary type is the most common, although all transitions from scirrhous to medullary are met with. It occurs as a nodular growth or a diffuse infiltration of the whole kidney. In the former, the shape of the kidney may be greatly changed, while in the latter its shape is retained. The origin is generally in the cortex, the parts first affected being the epithelium of the tubules; later the connective tissues become infiltrated. In the diffuse form are to be found many cavities of varying size, filled with broken-down tissue mixed with blood. This condition is likely to be misleading because of an indistinct sense of fluctuation being present. When the pelvis becomes involved, ulceration follows, and parts of the tumor separate and block the ureter. The capsule becomes thickened and very vascular. Adhesions to surrounding organs do not take place until late. When formed, the disease may extend to the overlying colon, into which the new-growth may even ulcerate. Secondary deposits form in distant organs, the retro-peritoneal glands, the liver, and the lungs. Rarely is the lower uninary tract involved in secondary infection. Dickinson explains this on the ground that infection takes place through the lymphatics, in which the flow from the kidneys is away from the pelvic organs.

2. *Lymphadenoma* occurs in the kidney as a part of a general disease; it is a metastasis, the primary growth being in the lympathic system, and consequently does not come within the sphere of the surgeon.

3. *Sarcomata.* Many of these are doubtless congenital. Of forty cases collected by Newman, thirty-three occurred under the tenth year, and of these thirty-three, twenty-six under the fifth year. Paul and Osler, as already referred to, have found them in the fetus. All varieties are found in the kidney. Their most frequent site of origin is in the cortex. At first the growth is encapsulated, but with cellular proliferation the capsule gives way, cell-elements find their way into the capillaries, and the disease becomes diffused throughout the entire organ. The richer the new-growth is in cellular elements the more rapid is this dissemination. Finally, the contents of the renal vein become infected and secondary deposits occur in the lungs.

The Symptoms are often very obscure. Renal symptoms may be wholly absent, the first thing to arrest attention being the discovery of a tumor in the lumbar region; or there may be anoxeria, with recurring attacks of vomitting or diarrhea, or even jaundice. Pain is not characteristic. It is not acute, but rather a feeling of discomfort, or of a dull, aching character, confined to the loin, seldom extending along the course of the ureter as in calculus, and uninfluenced by movement. Hematuria may be the first symptom and of such a degree as to produce syncope, as in a case recorded by Jones. It occurs when the growth has reached and ulcerated into the pelvis, and is hence absent in a great many instances. According to Roberts, it is absent in half the cases of malignant disease. When present it is continuous and independent of exertion, thus distinguishing it from the intermittent form present in renal calculus. It may also be absent for long periods of time.

When hematuria is the only symptom, the question presents itself: From which kidney does the hemorrhage originate? To decide this absolutely it is necessary to obtain samples of urine from either kidney. This has been accomplished in two ways: direct catheterization of the ureters, or compression of one ureter while the other remains

patent. Simon dilated the female urethra, and with the finger in the bladder he guided the catheter to the urethral opening. Pawlik accomplished the same without urethral dilatation by following certain landmarks in the anterior vaginal wall.

Newman introduced an electric lamp into the bladder, and with the aid of the eye introduced a specially devised catheter. Silbermann compressed one ureter with a rubber bulb filled with mercury; Tuchmann, by an instrument resembling a lithotrite, and Polk, by a catheter in the bladder and a finger in the rectum. Other devices have also been used. All have been reported successful, but none has come into general use, probably from the difficulties encountered in their employment.

The most important point, however, is the discovery of a tumor in the renal region. When of considerable size it can be easily made out by palpation, one hand being placed in front and the other in the lumbar region for counter-pressure. The tumor will be felt projecting forward and downward between the margin of the last rib and the crest of the ilium, smooth or irregular in outline, with rounded margins, and retaining more or less of the shape of the kidney; movable or not on deep inspiration, according to the presence or absence of adhesions, downward movement being most marked on the right side from the close relation of the organ to the liver. When of smaller size, Guyon's "renal ballottement" or Israel's method will be necessary. The former is practised with the patient recumbent. The operator stands on the side to be examined, and with the corresponding hand makes deliberate and gentle pressure at a point one inch below the junction of the tenth rib with its costal cartilage, and with the other hand pushed under the lumbar region, makes a series of gentle but short, regular, and quickly successive blows, by means of which the kidney is projected in a jerking manner toward the anterior abdominal wall. By the method of Israel,[9] the patient is placed in the lateral position with a pillow under the loin, the head-end of the table being elevated. Examination of the left kidney is made, with the patient on the right side, the operator standing upon the right side and placing the right hand upon the lumbar region, the left resting upon the anterior abdominal wall. During respiratory movements the finger-tips glide over the lower edge of the kidney. In the normally-attached kidney only the lower third, or at most the lower half of the organ can be palpated, and the rounded edge of the kidney can be felt and distinguished from the liver and spleen. These latter organs may be isolated and their edges lifted away from the kidney with the finger-tips. By means of this method Israel[10] diagnosticated in a boy, fourteen years of age, the existence of a normal kidney upon the one side and a sarcoma upon the other; in an emaciated woman with persistent hematuria, a calculus in the kidney was found and the diagnosis was confirmed by subsequent operation; and also a case of carcinoma in a patient twenty-one years of age, in which, with the finger pressed below the anterior junction of the eleventh and twelfth ribs, a flat prominence the size of a dime could be felt. In one month this had increased to the size of half a cherry; the kidney was exposed and exploratory puncture of the tumor proved it to be malignant. Nephrectomy was performed. The kidney was of normal size and microscopic examination confirmed the diagnosis, it being a carcinoma very rich in cells.

The retro-peritoneal location of the tumor is demonstrated by resonance on percussion anteriorly, from the interposition of the colon between the growth and the anterior abdominal wall. If the colon be empty, it will be felt as a rounded cord running over the front of the tumor. To exclude this, rectal insufflation with air should be used. If the colon is anterior, as it becomes distended, the percussion-sound will become resonant. When the tumor is of very large size the colon may be displaced inward; then there will be dulness instead of resonance, and a diagnosis must be reached by exclusion.

Diagnosis. — New-growths have to be distinguished from other forms of renal disease, affections of the peri-nephric tissue and supra-renal capsules, tumors of hepatic, splenic, or ovarian origin; tumors of the mesentery and pancreas, and fecal impaction. Before proceeding to an examination in any case it is advisable to administer a brisk cathartic. This will exclude one possible error of diagnosis, fecal impaction, and the empty condition of the intestine will render palpation more easy and accurate. Renal calculus is the most likely of renal affections to be confounded with new-growths. Both have the common symptom, hematuria. In calculus it is increased by exertion and diminished by rest. No such rule applies to neoplasms; it is often the reverse; the hematuria is "profuse, spontaneous, and recurrent" (Roberts), and independent of all external influences. Pain in calculus is more acute, boring, gnawing, or paroxysmal in character, and more diffuse, extending along the course of the ureter to the inner side of the thigh and testicle. Movement increases it. Pressure of the affected kidney is also more painful. In hydronephrotic and hydatid tumors fluctuation is more distinct than in the rapidly growing, malignant, and fibro-cystic varieties. Exploratory puncture will aid in the diagnosis. Careful examination and observation of the urine will exclude suppurative disease of the pelvis. From new-formations of the supra-renal capsule and peri-nephric tissue, or hyperplasia of the latter, a diagnosis is impossible. Horn and Bell and John-

ston[11] report three cases of adenoma of the supra-renal capsule; in one the kidney was not involved, but in the other two the growth had extended into the kidney. Knowsley Thornton, at the Clinical Society of London,[12] in 1890, reported the case of a woman, thirty-six years of age, with an abdominal tumor, which had been diagnosticated by Keith as an enlarged spleen, twelve months prior to its removal by abdominal section. After removal it was found to be a sarcoma of the supra-renal capsule, weighing twenty pounds, with a healthy kidney attached to its lower border.

Von Eiselberg[11] records a case of fibro-lipoma of the peri-nephric fat, the size of a child's head, firm and non-sensitive, removed along with the kidney. Harris[13] met with two cases in which hematuria was the only symptom. He explored the kidney, and found only thickening and adhesions of the peri-nephric tissue. The latter were broken up, and the hematuria disappeared.

Enlargements of hepatic and splenic origin are characterized by the absence of resonance anteriorly, from their close relation to the abdominal wall. On firm pressure the fingers can generally be pushed under the sharp margin of the liver, and in renal growths a space can be made out between the inner margin and the edge of the ribs. Movement with respiration has been considered diagnostic of new-growths in connection with the liver. This cannot be relied upon, because, on the right side at least, renal tumors of any size have this movement communicated to them through downward pressure of the liver. Splenic enlargements are more mobile, the greatest movement in renal tumors being in an antero-posterior direction (Hochsinger), and the notched margin of the organ can generally be made out. Renal tumors, when they extend inward to the middle line, and down toward the iliac fossa, have been most frequently mistaken for ovarian growths. Unless the bowel be adherent anteriorly, ovarian tumors are dull on percussion. Their intra-pelvic connection, or partial location within the pelvis, will exclude a renal origin, and resonance in the lumbar region is their characteristic.

Tumors of renal origin, however, at times possess all the diagnostic features of ovarian disease, as the following case, reported by Claus[14] at the German Congress of Surgeons, in 1885, illustrates:

"A woman, forty-six years of age, was healthy up to four years previously, when she noticed 'a rolling' in the abdomen, increased by deep inspiration and rapid movements. The abdomen grew larger, but for a considerable time there was no pain. A fluctuating tumor was felt in the middle of the abdomen. The urine was normal. The uterus was retroverted; only in front of this a pedicle could be felt. The diagnosis was monocular ovarian cyst. Celiotomy was performed, and the cyst was found to contain dark bloody fluid, and was connected with the kidney. Examination showed the tumor to be a fibroma, with few cells, but abundant fibers. It had developed between the medullary and cortical substance of the kidney, pushing the two apart. The cyst-wall was formed by the distended kidney-capsule."

Tumors of the pancreas and mesentery are retro-peritoneal. They are more centrally located, and their non-connection with the renal region can be shown by "Guyon's ballottement." In tumors of the pancreas, steatorrhea and the presence of sugar in the urine would aid in the diagnosis. Mesenteric tumors are very freely movable, as compared with renal tumors.

Failing to arrive at a satisfactory diagnosis, an exploratory incision for diagnostic purposes (which can be utilized as curative) can be resorted to. Either the lumbar or the transperitoneal route may be adopted. When the former, the kidney can be withdrawn in the loin, freely incised, examined by the finger from within and without, and again sutured without fear of any serious structural change. That such wounds of the kidney readily heal has been demonstrated experimentally by Schachner,[15] and confirmed by Morris[13] in the human subject, in the case of a man in whom the surgeon made an exploratory nephrectomy for calculus, and found none. The patient died a month later from another cause, and at the post-mortem the incision in the kidney was found represented by a linear scar extending through the renal cortex to the pelvis.

Hemorrhage after incision by the knife is rather profuse. To avoid this an opening may be made through the cortex with the Paquelin cautery. This is objectionable because it necessitates a temporary renal fistula when the conditions are such as not to demand a nephrectomy.

Treatment.—When the surgeon is reasonably satisfied of the existence of a new-growth, either benign or malignant, he is justified in making an exploratory incision, because it is impossible from the symptoms to differentiate the character, and as the majority are malignant, the element of success in the operative treatment depends upon early removal. In children under ten years of age the weight of opinion is against operative interference. Goodlee[16] believes that in the early stages it is justifiable, and the occurrence of secondary growths in only 28 per cent., as pointed out by Kühn,[17] would support this view. In 1885 Gross[18] reported a mortality of 57.57 per cent. in cases of sarcoma from the operation, recurrence in 42.58 per cent., and 35.71 per cent. well after thirty-one and a half months; and for carcinoma, 71.42 per cent. fatal.

Newman, in 1888, places the mortality for carcinoma at 56 per cent., for sarcoma at 53 per cent.

Fenger[19] cites eleven nephrectomies by Israel for malignant disease, with two deaths, a mortality of 18 per cent.; of the nine recoveries two died from relapse, one after six, and the other after three months. The other seven are now alive and well. Two of these may be considered as radical cures, as five and one-half years and four years, respectively, have elapsed since the operation—a percentage of 18 per cent. of radical cures. This is encouraging as to the result of early operative interference. The duration of life without operation is estimated at from two to two and one-half years. Of twelve cases of benign tumors tabulated by Newman, three died from the effects of the operation, a mortality of 25 per cent.

Nephrectomy may be performed by either the lumbar or the abdominal method.

1. *Lumbar nephrectomy.* The patient is placed on the side with the limbs well drawn up, and a firm, round pillow is placed under the loin so as to increase the space between the last rib and the crest of the ilium. Various incisions have been recommended, but that of König allows of most room. It commences about one inch below the margin of the last rib, is carried vertically downward along the outer border of the erector spinæ muscle to the crest of the ilium. If necessary to obtain sufficient room it is continued inward toward the umbilicus to the outer margin of the rectus and even through this to the middle line. The vertical part is completed first; then, after examination of the kidney, and if the needs of the case demand more space, the peritoneum is displaced forward and the muscles divided by a transverse incision. With broad and deep retractors the margins of the incision should be held well apart while the kidney is forced into the wound by pressure on the anterior abdominal wall. The perirenal fatty capsule, in the absence of inflammatory changes, can readily be detached by the index finger, the organ isolated and enucleated. The kidney is drawn well into the wound and forward toward the middle line. The pedicle is isolated and separate ligatures are passed around the vessels and ureter, and securely tied. As the vessels are being ligated all tension should be taken off the pedicle, which is divided close to the hilum, examined, and if deemed necessary, separate ligatures applied to the vessels of the stump. A large drainage tube is introduced into the cavity; if much oozing is present, it is preferable to pack with iodoform-gauze, and suture the incision. This König calls his retro-peritoneal lumbo-abdominal incision, in contradistinction to the retro-intraperitoneal lumbo-abdominal method. In the latter, when he desires to approach the tumor from the front, he divides the peritoneum in the line of the transverse incision.

2. *Abdominal nephrectomy*, or the trans-peritoneal method, when the incision is made through the anterior abdominal parietes. That with the incision in the linea semi-lunaris is known as Langenbeck's operation. The patient is prepared as for ordinary celiotomy, and after opening the peritoneal cavity both kidneys are examined manually. If one is found healthy then the other is removed through a vertical incision in the meso-colon over the renal region. With fingers introduced through this opening the kidney can be isolated as in the lumbar operation, the pedicle ligated and dropped back. Drainage can be effected through the lumbar region. The rent in the peritoneum is generally left unsutured, but it is safer to suture it, as Pugh[20] has recorded a case of death from obstruction due to strangulation of a loop of intestine in the peritoneal rent after extirpation of the left kidney for sarcoma.

Both operations have their advantages and disadvantages and their proper spheres of usefulness. To compare the subsequent mortality is no criterion, because it is the size of the tumor that necessitates the employment of the abdominal method. The mortality as given by Newman is 30.5 per cent. for the lumbar and 47.1 per cent. for the abdominal operation. The lumbar operation should be preferred in every case in which the size of the tumor will admit of its removal without undue force, or too extensive division of the abdominal wall. Advocates of the abdominal method lay great stress on being able to determine the exact condition of the other kidney. This can also be done in the other method by exposing the sound kidney through a lumbar incision on that side. It will not add to the danger of the operation, and the peritoneal cavity remains unopened.

I give the details of

A CASE OF SARCOMA OF THE KIDNEY; NEPHRECTOMY; RECURRENCE.

D. B., female, twenty-two years of age, was admitted into the Milwaukee Hospital August 23, 1890, with a diagnosis of renal tumor, probably a sarcoma, made by Dr. O'Malley and confirmed by Dr. Fox, in consultation. She gave the following history: For about two years she had suffered from dragging pain in the right lumbar region. This was marked by periods of paroxysmal exacerbation, accompanied by severe pain in the epigastrium, and vomiting. Such an attack continued for three or four days, during which time everything was rejected by the stomach. These attacks were attributed to disordered digestion and treated as such. They continued to recur and at shorter intervals. Five months before, while engaged in cleaning windows, she slipped and wrenched her right side. This directed attention to the lumbar region, where a tumor was discovered. This tumor had gradually increased

in size, and with the increase there were more frequent attacks of pain in the epigastric region, and accompanying vomiting. There is no history of urinary disturbance beyond increased frequency of micturition prior to menstruation, which has always been regular, but during the past six months of diminishing quantity.

The patient is anemic, but fairly nourished; she has lost in past years about eight pounds in weight. Inspection reveals a fulness in the right lumbar and umbilical regions, and on palpation, an oblong tumor, extending from the right renal region posteriorly to a point beyond the middle line and below the umbilicus, can be made out. The lower end of the tumor is rounded and smooth; the upper, under cover of the costal arches, is larger and nodular. The tumor is freely movable and can be separated from the liver on the right side. It gives an indistinct feeling of fluctuation. On percussion, dulness is found to extend from the middle line just below the umbilicus, backward to the lumbar region, continuous with the liver-dulness, laterally and posteriorly, separated from it anteriorly at a point midway between the middle line and the costal arch. Rectal insufflation of air diminished this area of dulness anteriorly, and thus demonstrated the retroperitoneal location of the tumor. For ten days prior to the operation the urine varied in quantity from 16 to 32 ounces daily, was of a specific gravity of 1020, contained a trace of albumin, and numerous small decolorized blood-corpuscles and bladder-epithelia.

The operation was performed September 3, 1890. On account of the large size and great mobility of the tumor, the abdomen was opened in the middle line. The left kidney was found to be apparently healthy, but enlarged, the ascending colon displaced inward, and the new-growth in contact with the abdominal wall anteriorly. The ascending colon was now dragged as far as possible toward the median line, a small slit made in the peritoneum to its outer side, and through this the tumor was gradually enucleated by the finger. During enucleation numerous large vessels in the perirenal fat required ligation. The ureter was first ligated low down and cut through. On ligating the vessels the patient suddenly ceased breathing, but rallied soon under artificial respiration and stimulants hypodermatically. After section, the renal vein was found to contain partially coagulated blood. The pedicle was dropped back, the rent in the peritoneum left unsutured, no drainage provided, and the abdomen closed. For the first three days following the operation the patient suffered from one of her usual attacks of colic, epigastric pain, vomiting, etc. Beyond this, recovery was uneventful.

The tumor as removed weighed eleven pounds, was covered throughout by large veins, firm and smooth at the lower pole, semi-fluctuating and nodular at the upper. On section, the upper part was found made up of cavities of varying size, filled with dark sanguineous fluid, or partially coagulated blood. No kidney-substance remained. The lower or solid part contained considerable kidney-substance, and, in the center, a fatty tumor undergoing degeneration. Microscopic examination showed it to be a round-celled sarcoma.

Subsequently the patient considered herself well for about six months, when she had an attack of influenza. Persistent cough followed this, and later her old attacks of colic reappeared. She was readmitted into the hospital July 1, 1891, when examination revealed a recurrence of the disease in the pedicle; also a small nodule of the same character at the lower angle of the abdominal incision, and numerous crepitant râles throughout the whole chest. She died September 1, 1891. At the necropsy the condition as stated was found, and in both lungs multiple and disseminated secondary growths in all stages of degeneration. The left kidney was one-third larger than normal; the other organs were healthy.

PAPILLOMA OF THE RIGHT KIDNEY; NEPHRECTOMY.

A. S. (first seen in consultation with Dr. Lang, November 28, 1892), twenty-six years of age, the mother of two children, the youngest one and a half years old, dates her trouble back to her last pregnancy. During the period of gestation she had occasional uncomfortable sensations in the right lumbar region. After her confinement these disappeared, only to recur early in the summer of 1891. In August, 1892, she first detected, under the right costal margin, a tumor, which was diagnosticated by Dr. Lang as a floating kidney. As the kidney was not very movable, he directed that a snug bandage should be used. This gave temporary relief. Still the tumor steadily increased, and became more movable. About the same time, and two days prior to her menstrual period, she had an attack somewhat resembling renal colic, with hematuria. These attacks have recurred regularly at this time since. In the interval urine is always free from blood. The patient is certain that there is no variation in the size of the tumor, or in the discharge of urine, during these attacks. Menstruation is regular. The woman was always healthy. One brother died of sarcoma of the thigh.

The patient was very anemic, having had a very severe attack of hematuria November 28, 1892, the urine appearing as if pure blood, and being of a deep smoky tinge. Examination of the abdomen showed a tumor to the right of the middle line and on a level with the umbilicus. It was freely movable in an antero-posterior direction. In size it was three times as large as a normal kidney, thickened from before backward; the pelvis and both poles could be made out. On December 1st she was admitted into the Milwaukee Hospital, when it was found that rest in bed had no influence on the character of the urine. On the 4th, she began to menstruate, after which there was less blood in the urine. The daily average of urine voided for nine days was 43 ounces, the maximum being 56 ounces, and the minimum 36. The probable diagnosis was sarcoma.

Operation was undertaken December 10, 1892, under chloroform-anesthesia. The kidney was exposed by König's incision. Exploratory puncture with a hollow needle failed to reveal anything. The needle was followed by ignipuncture, with the Paque-

lin cautery, and digital exploration of the interior of the kidney. The exploring finger detected soft, broken-down tissue, surrounded by an apparently firm wall. This opening was tamponed with iodoform-gauze, an additional forward transverse incision made in the soft parts, and the kidney removed. The incision was closed by deep sutures of catgut and superficial ones of silk. On the first day following the operation, 21 ounces of urine were voided; on the second, 32; on the third, 29; on the fourth, 35; and thereafter the quantity ranged from 32 to 36 ounces. Primary union of the incision occurred. The patient was kept in the recumbent position for four weeks to insure firm union of the incision, and thus guard against the occurrence of a ventral hernia. Rapid improvement of the general health followed and has continued.

The kidney weighed one pound and three-quarters. On splitting it open longitudinally a rounded tumor the size of a tennis ball was found occupying the lower half of the medullary portion, and extending into the pelvis as a soft papillomatous mass. The pelvis was filled with coagulated blood, and two smaller papillomata were found springing from its upper part. A great part of the tumor consisted of disintegrated coagulated blood, on washing which away, the papillomatous character of the new-growth could be demonstrated. The cortex of the kidney was healthy, but somewhat atrophied from pressure over the most prominent part of the tumor.

PNEUMONIA AMONG THE INSANE.[1]

By ELIOT GORTON, M.D.,
ASSISTANT PHYSICIAN TO NEW JERSEY STATE HOSPITAL AT MORRIS PLAINS, NEW JERSEY.

From March 1 to April 25, 1893, we were afflicted with an epidemic of pneumonia following influenza, during which time there came under my personal observation and care 63 cases of pneumonia, all among the female insane and their nurses.

I should deem myself culpable did I not take this opportunity of placing before the medical profession a summary from the records of these cases, many of which were typical and need no special mention, while a few others were so obscure and misleading as to symptoms that the disease—while suspected by reason of the already large number stricken—could not be diagnosticated by any objective symptoms present, and it was left for the autopsy to establish the diagnosis. The hope that a summary of 63 cases of pneumonia may not be entirely devoid of interest to the profession at large, constitutes my apology for this paper.

A peculiar phenomenon in relation to this epidemic is the fact that for the first three weeks it was confined exclusively to the female wing of the building, not a single case of influenza appearing in the male wards during that time. While the disease was at its height among the females, the male side of the house was enjoying its usual good health, and when the disease finally did gain access thereto there were comparatively few cases, with not more than eight cases of pneumonia. The fact that this institution is all under one roof; that the male and female departments are exact counterparts, of similar structure, heated and ventilated in precisely the same manner, must also be borne in mind.

The etiology of pneumonia is at present an all-absorbing and disputed question, though the theory of a specific origin is becoming almost generally accepted. The pathologic investigations and experiments conducted during the past two years seem to indicate that we must give up our previously-conceived ideas as to causation, accept the pneumonia-coccus of Fraenkel, and class pneumonia among the acute infectious diseases.

While in the light of recent pathologic researches I am prepared to accept this theory, the question constantly forcing itself upon my mind is: Is it not possible and probable that we may have a specific and a non-specific form of this disease? It would seem to be without doubt, from my recent experience, that the epidemic form of the disease is of specific origin, yet I cannot at present bring myself to believe that every case of sporadic pneumonia

---

1 Throughout this article reference is made entirely to croupous pneumonia.

met with in ordinary practice is due to a specific organism and is infectious.

We have Asiatic cholera, and no one doubts for a moment its specific and infectious nature. We also have cholera morbus, or cholera nostras, a disease so identical with the first named, that in severe cases the microscope is a necessary adjunct to a differential diagnosis; yet, except it be during an epidemic of Asiatic cholera, no one pretends to confound the two. Why, then, may we not have two forms of pneumonia, identical in clinical manifestations, yet widely divergent as to cause?

Again, pneumonia is distinctly a disease in which one attack predisposes to another, and one individual may have any number of attacks, while in most all other acute infectious diseases of specific origin, one attack usually grants immunity from a second. The epidemic form of the disease would point strongly toward an acceptance of the theory of specific origin without any further question, but pneumonia is seldom epidemic in character, and when so, is usually more malignant and therefore more fatal than in those cases that we term sporadic, and it is so probably by reason of a specific organism. In these latter cases may not the pneumonia-cocci found in the sputa be rather a sequence of the inflammatory process than the cause? While the recent experiments of Kitasato, Behring, and the Klemperers seem to support most strongly the theory of specific origin, and they show apparently that they have granted immunity from the disease by the injection into the blood of pneumotoxin, yet in two cases about to be related in which there was undoubted pneumonia, and which made a good recovery—the lungs becoming clear and the patients resuming their work at the end of two weeks in one case and of three weeks in the other—they became reinfected, and both cases died within three days after the second infection. Yet, according to our pathologists, these cases should have been proof against reinfection for at least six weeks. However, whether pneumonia is or is not always of specific origin, the question still remains to be definitely determined, and there is no doubt in my mind but that there are more individual causes of pneumonia than are or ever will be known to medical science.

The weather of February was cold and raw, while that of March was clear and unusually mild, though with cold winds. If atmospheric or telluric conditions play any part in the causation of pneumonia, the rather sudden change in our climate about the first of March may have been an important factor, for it was just at this time that influenza made its appearance. Yet, if so, how can we account for the fact that for so long it was confined exclusively to the female wing? This is suggestive that the cause may be looked for in some defective sanitary condition of that side of the house, though so far as is known at present the plumbing, system of sewage-disposal, and general sanitary condition of the house were never better. If we may still consider atmospheric conditions as a cause, our system of ventilation—that of drawing in air from the outside and forcing it through the wards to an exit in the roof—must be taken into consideration, and also in this connection, the overcrowded condition of the hospital. It would be interesting to know why all of these cases were preceded by influenza, and why there should have been 63 cases of pneumonia among the females and but 8 among the males. Does the presence of this catarrhal affection render individuals more susceptible to infection—the inflamed mucous membrane with its altered secretion becoming a culture-medium for the pneumonia-cocci, the development of pneumonia depending upon individual predisposition, aided, perhaps, by certain atmospheric conditions with which as yet we are not familiar?

Whatever may be the cause, we have to deal with the fact that on or about March 1, 1893, influenza of a most severe type made its appearance in the hospital, and made no distinction in its ravages between the sane and the insane. Among the patients and nurses in the female department there were 176 cases of influenza, followed in 63 cases, or nearly 36 per cent., by pneumonia.

As a matter of convenience, I have grouped the cases in four classes, as follows:

Class I, typical cases, of which there were 24; Class II, cases in which the usual premonitory symptoms were absent, of which there were 33; Class III, cases in which there were no objective symptoms, of which there were 4; Class IV, cases in which the physical signs were present, with no special disturbance of temperature, pulse, or respiration, of which there were 2.

CLASS. I.—In every case the patient suffered from influenza, complaining of intense boneache, headache, backache, creeping chills, and coryza. The temperature ranged from 100° to 102°, and the pulse from 90 to 120. The acute symptoms subsided on about the third day and the patients felt much better—so much better, in fact, that in the morning many left their beds against my advice—when toward evening or late in the evening, they were again seized with a severe chill lasting from five to fifteen minutes, the temperature rising to 104° or 105°, the pulse to 120, and they complained of a sharp, stabbing pain in the chest. The respirations were accelerated, and there was a cough, short, hacking, and suppressed, with very little expectoration of a frothy, tenacious mucus, which in a few cases was blood-tinged. On the second or third day the sputa became "rusty-colored," the physical

signs developed, and the patients presented the characteristic pneumonic appearance, with flushed and anxious countenance, temperature 102° or 103° in the morning, and from 103° to 105° in the evening; pulse from 100 to 110 in the morning, and from 120 to 130 in the evening; respirations from 40 to 60 and shallow; great restlessness and sleeplessness; anorexia, constipation, thirst, and coated tongue. The pain in the chest in most cases disappeared on about the fourth day, while in others it persisted throughout the entire illness and with such severity that it became necessary to use hypodermatics of morphin for its relief. In these 24 cases, the crisis occurred on the sixth day in 3; on the seventh day in 10; on the eighth day in 4; on the tenth day in 2; and 5 died on or about the ninth day of the disease at an average age of sixty and three-fifths years, the youngest being forty-six and the oldest seventy-four. The average age of the nineteen recoveries was forty-five. Of these cases the right lower lobe was affected in 9; the left lower lobe in 6; both lower lobes in 2; the entire right lobe in 2; the entire left lobe in 1; the left apex in 2; the right apex in 2.

One case in particular deserves more than passing notice: On the fifth day of the disease one of the nurses, whose left lower lobe was affected and whose symptoms were all favorable, was seized with an urgent desire to defecate while the nurse in attendance was busy with another patient. She therefore disobeyed orders, and getting out of bed to use the commode, was taken with a violent chill. Her temperature, which had been 102°, rose to 105°, and in a few hours she complained of intense pain in her right side. On the following day the physical signs showed an extension of the inflammatory process to the right lower lobe, while the left was resolving. The expectoration became prune-juice in color, and on the morning of the third day thereafter, her temperature was 105°, pulse 160, respirations 65, with extreme dyspnea, cyanosis, delirium, picking at the bedclothes—in fact, symptoms of approaching death. Nitro-glycerin and strychnin were administered hypodermatically, and brandy and aromatic spirit of ammonia internally, with the effect of lowering the pulse to 150. Sponging with equal parts of alcohol and cold water reduced the temperature to 103° (sponging was resorted to whenever the temperature reached 104°), and oxygen gas was given for five minutes every half-hour. These methods were kept up for two days and nights, during which time her pulse continued at 150 and respirations at 60, when the crisis occurred, the temperature fell to normal, the pulse to 96, with a general subsidence of the alarming symptoms. However, at the end of two days her temperature again rose to 102° and her pulse to 120. Examination revealed an extensive effusion in the right pleural cavity which at the present writing (May 6th) is not wholly absorbed, and the patient, while extremely weak, is gradually regaining her strength.

Class II.—As previously indicated, the usual premonitory symptoms of pneumonia were absent, and with the exception that in many there was also no pain, they were identical with those of Class I.

All suffered with influenza, but it was not until the fifth day that the physical signs of pneumonia developed, respirations became accelerated, and the sputa blood-tinged. There was no initiatory chill followed by a sudden rise in temperature; the pulse continued at from 100 to 120; except in a few cases no pain was complained of; the tongue, though coated with a white fur, was moist and the expectoration previously to the fifth day was bronchitic in character. Of these 33 cases, 5 were under thirty, 18 over fifty, and 10 over sixty years of age. Six died, of whom 2 were over seventy, 1 was fifty-one, and 2 were epileptics at twenty-seven and twenty-eight years of age. The average age at death was forty-nine and a half years.

Class III.—The four cases of this class were patients in the last stage of dementia, and were in an extremely adynamic condition owing to their want of exercise and long confinement. Their lack of vitality rendered them easy victims to the disease, and it is hardly to be wondered that their symptoms were not pronounced, and that they succumbed to the disease. But for the fact that others in practically the same mental and physical condition contracted pneumonia and presented the usual symptoms, these would not be mentioned. I am frank to admit that had these cases come under my observation during a season of health, it would never have occurred to me to suspect pneumonia, for there were absolutely no objective symptoms, and if influenza developed previously to the pneumonia no one ever knew it. The patients simply did not feel well, and so stayed in bed. In no case was the pulse over 100, or the temperature over 102°, but in all the pulse was small, weak, and compressible. There was no cough, no expectoration, no pain, no acceleration of respiration, no dyspnea, no cyanosis. Exploration of the chest gave a practically negative result, and the physical signs were so obscure that a positive diagnosis of pneumonia could not be made. It was merely suspected, and the autopsy confirmed the suspicion. The inability to obtain clear and unmistakable physical signs in these cases may be attributed to their slow manner of breathing, for in counting the respirations the movement of the chest-walls was almost imperceptible.

Niemeyer, in his *Text-book of Practical Medicine*, vol. i, page 179, says: "In aged persons or subjects of depraved constitution . . . . many have no characteristic sputa; nor do they complain

either of dyspnea or pain . . . . the physician having been deceived by external appearances, which really bear greater resemblance to typhus than to pneumonia of vigorous adults, and having neglected to make a physical exploration of the chest."

To me these cases were interesting and instructive, and I am now convinced that many of the aged and feeble dements who die from no apparent cause except a gradual failure of the vital powers may die instead from asthenic pneumonia.

These four cases were aged respectively fifty, fifty-one, fifty-two, and sixty-two.

CLASS IV.—These two cases were peculiar and interesting from the fact that the temperature ranged from 97° to 99°; the pulse from 70 to 80; respirations from 16 to 24. In both, a small portion of the right lower lobe was affected; both, it may be well to say, were nurses, one of whom suffers from an organic lesion of the heart. The characteristic pneumonic sputa and pain were present, lasting about three days. Yet, when these patients were considered well enough to leave their beds, on assuming the upright position the pulse ran up to 120, and the feeling of nervous exhaustion and prostration was extreme. They made a slow recovery and were among the last to have again the feeling of well-being. I am unable to account for the clinical phenomena presented by these two cases, except it be on account of the small area of lung involved. Yet we know that often in such cases the severity of the symptoms is out of all proportion to the amount of lung-tissue involved.

Of the two cases alluded to previously who became reinfected, little need be said. One was a case of senile dementia, aged seventy-four, who was one of the first to contract pneumonia. From the first attack she apparently made a good recovery, and was about the ward helping with the work. Three weeks later she again developed the disease, and from the beginning her symptoms were extremely grave and pronounced. She died on the third day. The second case was that of a colored woman, aged fifty-one, who had been admitted to the hospital a short time previously, suffering from acute mania. As she recovered from her period of excitement she contracted pneumonia and recovered by lysis—the only case of recovery, strange to say, which did not terminate by crisis. She was apparently well for two weeks, when she again contracted pneumonia and died on the third day of the disease.

Complications. The complications in the whole number of cases were comparatively few, though not unimportant. An exhausting diarrhea requiring treatment was present in three cases; jaundice appeared in one; pericarditis in two; pleurisy developed in two-thirds of the cases, and meningitis was entirely absent. In no case was delirium a marked symptom.

Sequelæ. About one-half of these cases made an uninterrupted recovery. The remainder were left in an extremely nervous, weak, and prostrated condition, from which they recovered slowly. In several otitis media developed, and in a few others symptoms of heart-failure occurred when they attempted to sit up in bed; symptoms of nervous prostration were severe in all.

Mortality. When we take into consideration the fact that fifty-five of these patients were afflicted with the various forms of insanity; that a few, owing to their delusions, were difficult to manage, and (owing to the number of nurses sick) could not be constantly watched, it is surprising that the death-rate was not higher.

Of the 15 deaths, 11 were cases of senile or terminal dementia; 3 of epileptic dementia; 1 of recent acute mania. It will therefore be seen that death took place in those patients whose vitality was at a low ebb, and who, enfeebled by age, by epilepsy, by sickness, and by long confinement, were in no condition to withstand the ravages of a disease acknowledged by all authorities to be one of the most fatal of the acute diseases.

The ages at death in the 11 cases of senile or terminal dementia were as follows: 60, 46, 74, 50, 52, 70, 67, 62, 50, 73, 51. The average age was $59\frac{6}{11}$. In the 3 cases of epileptic dementia the ages were 27, 28, 65; of the cases of recovery from acute mania, 51.

SUMMARY.

Influenza	176 cases.
Pneumonia occurred in { patients, 55 / nurses, 8 }	63 cases, or 36 pr. ct.
Deaths from pneumonia (all patients)	15 cases, or 23.8 pr. ct.
Average age at death . . .	55 years.

Treatment. Since the days of Rasori, when pneumonia was treated by bloodletting and two-scruple doses of digitalis, and patients were bled daily until either their symptoms became more favorable or they died, we have steadily advanced; and as our knowledge of pathologic anatomy has become more exact, we have come to a more conservative and rational method of treating pneumonia.

The expectant plan of treatment now almost universally in vogue, since physicians have accepted the fact that pneumonia is an acute self-limiting disease, still has for its opponents those who hold that, in the beginning, antiphlogistic and depleting methods of treatment exert a favorable influence upon or abort the disease.

Whichever method is the more rational—and from personal experience I can testify to the greater

efficacy of the expectant plan—our text-books, while agreeing that the indications are to keep the temperature within bounds and to support the heart, are not altogether agreed as to the better way of accomplishing the desired result. Some recommend quinine in large doses at the beginning; others have their own favorite antipyretics, while, to support the heart, digitalis and alcohol have been extensively used.

Dr. Osler[1] says: "No certainty has as yet been reached as to the value of digitalis in the failing heart of fever. The practice is very general, but it is a drug to be used with caution in this condition." Niemeyer[2] says: "Digitalis has been extensively employed and with great justice in the treatment of pneumonia . . . . with a pulse of from 100 to 120 in frequence."

The physiologic action of digitalis is "to prolong diastole, increase the vigor of systole, and increase arterial tension." Again, to quote Niemeyer, page 174: "The small soft pulse is due, not to weakness of cardiac contractions, but to lack of blood in the left ventricle, which causes a deficit in the supply of the aortic system. The left ventricle is imperfectly filled because afflux of blood to it is obstructed."

Patients with pneumonia, except when an unusually large amount of lung-tissue is involved, die at the heart and undoubtedly because the heart is in a great measure deprived of its necessary rest and nutrition, and the heart-muscle itself is disorganized by the high temperature to which it is subjected for so long a time. It seems to me, therefore, that in the rapid pulse of pneumonia, great harm can be done by the administration of digitalis, for the heart, already weak from overwork, is made still more so by that drug. The effect of digitalis is to temporarily lower the pulse-rate *and increase the vigor of the contractions*, thereby really *increasing* instead of *diminishing* the work the heart has to do. The obstruction in the lungs is not removed, arterial tension is increased, and when the effects of the drug wear away the heart is left much weaker than before. I am indebted to Dr. Thomas P. Prout, pathologist to this hospital, for the statement that in 30 per cent. of his autopsies on the insane the heart was in a state of marked fatty degeneration. In this condition, so predisposing to heart failure, digitalis would certainly be an unsafe drug, and it is a condition which should always be borne in mind, even in the treatment of the sane. In my experience with this disease, nitro-glycerin in small doses, repeated often if necessary, has been more than a substitute for digitalis, and I have been more than pleased with its effect. In every case in which it was used the pulse-rate slightly diminished in frequency and arterial tension was lowered, thereby temporarily relieving some of the strain upon the heart and also relieving collateral hyperemia. Strychnin, as a nerve and cardiac tonic, in doses of from one-sixtieth to one-thirtieth of a grain, repeated every two hours and oftener if necessary, cannot be too highly extolled, and in my opinion alcoholic stimulants are indispensable.

My own cases, with two exceptions, were treated on the expectant plan. Jacket poultices of flaxseed meal, renewed as often as they lost their heat, were applied and covered with cotton batting. As an expectorant (or placebo), ammonium chlorid in brandy was given in small doses every two or three hours. Aconite and veratrum were also used at the beginning, but with no appreciable effect. Patients were confined to a diet of milk, eggs, and beef-tea, and the bowels were kept open by the use chiefly of warm-water enemata (glycerin suppositories were used in a few cases with negative results). In the few cases in which the temperature had a tendency to rise above 104°, sponging with equal parts of alcohol and cold water was resorted to with excellent results. No antipyretic medicines were used, except at the commencement of the influenza, when a few powders, containing five grains each of antipyrin and phenacetin, were given to relieve the distressing aching. Morphin hypodermatically in one-fourth grain doses was given unhesitatingly when necessary for the relief of pain, with no unfavorable result. From the fourth day the patients were given strychnin sulfate, from one-sixtieth to one-thirtieth of a grain, with two drams of brandy every three hours, and these two remedies were increased or diminished in amount and frequency, according to the indications. Caffein citrate in from three-grain to five-grain doses, was used in a sufficient number of cases to convince me that it is a remedy of little value in this disease. In severe cases, with flagging heart, aromatic spirit of ammonia, with brandy, was given in connection with the nitro-glycerin and strychnin. In two cases, both nurses, one of which has been related at length, oxygen gas was also used, with the effect of relieving the cyanosis and dyspnea and lessening the rapidity of the respirations while being inhaled, but it did not lower the pulse-rate except in one instance, and I should wish to give it a more extended trial before expressing an opinion as to its value. It certainly did some good, and it seems to be a rational means of treatment, but many opinions have been expressed both for and against its use.

The two exceptions to this plan of treatment spoken of were given at the beginning ten grains of calomel, followed in six hours by a saline. Both

[1] In his recent Practice of Medicine, page 531.
[2] In his Text-book of Practical Medicine, vol. i, p. 191.

cases died, but I do not by any means attribute their death to the initial treatment. I may also add that I have never seen any benefit from this method of treatment, and it does not seem reasonable to suppose that in any disease in which all the indications are to support the patient, exhausting measures, either at the beginning or at any other time, can abort the disease or be of any benefit to the patient.

RUPTURE OF THE URETHRA IN THE MALE.[1]

BY CLINTON B. HERRICK, M.D.,
ASSISTANT ATTENDING SURGEON TROY HOSPITAL, PHYSICIAN AND SURGEON COUNTY HOSPITAL, TROY, N. Y.

RUPTURE of the urethra may be produced by causes both internal and external. Those internal may be mentioned as foreign bodies coming from the bladder, as calculi; or such bodies from the outside, as catheters, sounds, or other bodies introduced through the meatus. The external causes are chiefly, the falling astride of something, kicks or blows upon the perineum, or wounds inflicted by sharp instruments. Another cause may be a primary stricture in the urethra, with damming back of the urine, followed by distention of the canal above the point of stricture, with consequent ulceration and perforation. Some of these causes may rupture the urethra instantly, while others lead to it by the steps of ulceration and perforation.

The symptoms of rupture of the urethra are pain, inability to pass water through the meatus, dribbling of urine through the external wound, if such be present, and later, inflammation, swelling, and suppuration in the perineum. Either or all of these symptoms may be present in varying degrees. The location of the rupture and its extent modify the symptoms. For instance, if it occurs in the spongy portion of the canal, little or extravasation occurs; nor are any of the symptoms severe, for here the canal is surrounded by contractile and muscular tissues that offer resistance to extravasation. No symptom but pain may follow rupture confined to the prostatic portion. All such injuries in the membranous part of the canal, however, are usually followed by the more intense symptoms because of the cellular tissues that fill the perineum.

Having a patient in such a condition that the symptoms lead us to believe that his urethra is ruptured, the first course to pursue is to find out if the canal is continuous and open from the meatus to the bladder. Here it is that great care should be exercised. If the history shows that a foreign body has been introduced from without and lost, or that a non-traumatic obstruction has suddenly appeared, the exploring sound or catheter must be introduced very slowly, so as to detect the obstruction when it is felt, and not to push the body further toward the bladder. Occasionally the body may be felt by palpating the penis; the sound may then be dispensed with. If the body be encountered in the pendant portion, the penis should be grasped beyond the body, and with proper forceps the attempt at removal be made. In case this is not such an instrument as a hair-pin or a pig-tail, which slips in more easily than out, it is very probable that, with patience, it can be removed. When not successful, however, no delay should be allowed, but the operation of perineal section should be performed at once.

Again, a stricture may be met in the portion of the canal external to the rupture. If this be all, or part of the cause, it should, before proceeding, be freely broken up, either by divulsion or division. But, the exploring sound may pass with little or no obstruction into the bladder, in cases in which the rupture is slight, caused perhaps by a puncture, or by mal-instrumentation. This condition is the most favorable, and if here the urine flows freely by the meatus, it is quite proper to allow it to do so, and watch the case carefully for perineal symptoms. The cases that we more commonly meet with, however, are those in which the symptoms are present in their greatest intensity, when the exploring sound refuses to pass into the bladder, when there is evidence of severe laceration of the urethra, either from internal mal-instrumentation or external straddle-falls. When we meet with these cases we must not wait for anything, but proceed immediately to perform perineal section. Extravasation occurs so quickly, and is so disastrous in its effects and results, that delay means ulceration, suppuration, and absorption of poisonous urea and pus.

Perineal section means opening of the perineum without necessarily going any deeper. When the incision is carried into the urethra, it becomes an external perineal urethrotomy. In either case a perineal section is the first step, and whether or not the following steps convert this into an external perineal urethrotomy depends on the condition of the parts.

The operation of perineal section is performed as follows: Placing the patient upon the table in the lithotomy position, and having straps or assistants to hold the flexed legs firmly and widely apart, the perineum is scrubbed and shaved, and the patient fully anesthetized. I do not believe a sound in the urethra is of any service. Anyone with a knowledge of the anatomy of the parts will experience no difficulty, the only vessels of size to be avoided being the arteries of the bulb, and if the incision is carried down exactly in the raphé these will not be disturbed. The scrotum should be held up by an assistant, who is careful to keep the raphé line constant and steady. When extravasation has existed for any length of time, the knife will very soon

[1] Read before the Med. Soc. of the County of Rensselaer.

enter a cavity, from which urine, and perhaps pus, will gush. If this does not take place, the incision should be carried down, using director and retractors carefully placed, until the urethra is reached. This is recognized by its cord-like character, or by the bulging of the foreign body, if one be present. The urethra may then be incised, and the foreign body removed.

If the urethral rent be easily found, a second opening should not be made, and the foreign body should be coaxed along to the rent, and there removed. In any case the wound should now be thoroughly washed out with an antiseptic solution, preferably mercuric chlorid (1 : 2000 or 1 : 3000), and the cavity searched for foreign substances. A soft rubber or silk catheter should now be passed through the meatus into the bladder. This may be an easy matter if the rent is slight; but if the urethra is lacerated or torn across it becomes a very difficult procedure. The catheter should be passed in at the meatus until it appears in the perineal wound, when attempts should be made to guide its point into the bladder. Success may attend the procedure by passing one catheter from the wound into the bladder, and a second larger size from the meatus to the wound; then telescoping the smaller into the larger one, the former may be carefully drawn and pushed through the urethra from behind forward. At any rate, the opening into the bladder is there, and can be found by perseverance and patience. In case one tires before discovering this, it can be left until later, when granulations fill in around it and it can be readily seen. Attempts should be made daily, however, until it is found and a catheter introduced. The bladder should now be washed out with a borac acid solution.

As to the after-care, it is my practice to leave a soft catheter *in situ*, from meatus to bladder, for the first forty-eight hours, for by so doing the severed ends of the urethra become somewhat fixed and approximated in the wound. A peculiar affinity seems to exist between the severed ends of the urethra, and they will frequently adhere to each other with surprising rapidity. The perineal wound should be carefully attended to daily, packing with iodoform-gauze being preferable.

The catheter should be removed in forty-eight hours, boiled and reintroduced; this will now be done with much greater facility than before. After a few days or a week this can be dispensed with and the urine allowed to pass, pressure on the perineal wound assisting its escape by the proper channel. It is needless to add that we should look well after the constitutional symptoms of our patient, using antipyretics and supporting measures as indicated until fever subsides; even for some time afterward tonics are indicated, and should be judiciously employed. Urethral fever should also be guarded against, even in slight cases, as this in itself not infrequently leads to a fatal issue. Full doses of quinine will usually abort this.

As to the final result in these cases, much depends on the cause and extent of the trouble. If slight, there will probably be no trouble whatever. A sound should be passed at intervals to guard against cicatricial contractions, and, as a rule, complete recovery ensues. Occasionally the fistula refuses to heal, or delays a long time; but this is exceptional. In such a case I should advise slight curettings and firm pressure. We meet with cases, however, in which the extravasation and suppuration with absorption have been so extensive that the patient is in a very bad condition when first seen, and frequently succumbs quickly. It is always better to give a guarded diagnosis.

I shall briefly relate a few cases that I have encountered and which will be examples of the various causes and conditions already described.

Case I.—Aged thirty; admitted into the County Hospital, with the history of having fallen across some beams. When seen he was in a very bad condition, in fact, almost in a state of collapse. The perineum and scrotum were greatly distended and ecchymosed. Very little urine dribbled through the meatus, and the bladder rose high over the pubes. He was prepared for operation and anesthetized at once, and an incision made directly into a cavity from which urine gushed. A catheter was easily passed from the wound into the bladder, with partial relief. The catheter was left *in situ* and the urine was permitted to dribble through. The patient, however, sank rapidly and died on the following day.

Case II.—Aged about thirty; was admitted into the Troy Hospital, with the history of having received a pitchfork-stab in the "crotch," followed by swelling. He was in a bad condition, and it was impossible to pass a catheter, by the way of the meatus, into the bladder. Others had made the attempt before and left their results. Perineal section was performed at once, and the urethra was reached without difficulty, as it was easily recognized by its cord-like feeling. The soft parts had not broken down, but were very edematous. The urethra was opened in the line of incision and a catheter was passed into the bladder. Although everything was done for the man, he died.

Case III was seen in consultation at Cohoes. Three days previously the man had fallen astride some planks. Such symptoms soon followed as retention of urine, pain and swelling in the perineum, etc. Attempts to pass a catheter failed. The following day the scrotum and penis began to swell, and, continuing, soon reached an enormous size, with ecchymosis extending to the inside of the thighs. Punctures in the scrotum allowed gas and fluid to escape. Perineal section was performed on the fourth day after the injury, the incision soon reaching a cavity and showing the tissues of the perineum disintegrated. Some urine

escaped. It was with great difficulty that a catheter was passed into the bladder, and a large amount of urine evacuated. The urethra was found to be torn completely across, and the inner end lay free in the wound, entirely separated from its contiguous tissues. The bladder was washed out, and a catheter was left *in situ*. The condition of the patient had been bad from the beginning, the pulse small and weak, and the skin clammy. He rallied, however, and reaction became fully established. He finally recovered, but to show how disastrous extravasation is, abscesses finally developed in both groins, the scrotum sloughed so as to lay bare the testes, a slough occurred at the junction of the penis with the scrotum, and a second fistula appeared. At the present writing the man is improving rapidly, and urine is passing freely through the meatus with the fistula closing rapidly.

In the three cases just given the injury was of an external nature, causing the rupture; the following are examples in which an internal cause was present:

CASE IV, aged sixty-five, was admitted into the Troy Hospital with the history of having five days previously introduced a lead pencil into the urethra, which had slipped from the man's grasp. After a while, pain became so severe and micturition so difficult that he sought relief. When the sound was passed into the urethra it encountered the foreign body in the membranous part of the canal. It could not be grasped. Perineal section was performed at once, and the scalpel soon reached the side of the pencil, whose peripheral end lay in a suppurating cavity. It was removed and the cavity and bladder washed out. The pencil was five inches long, and incrusted on its inner end. Bleeding was profuse from the bladder, and this nothing seemed to control. The catheter was left *in situ*, but soon became blocked. The patient succumbed the following day. The necropsy revealed a perforation in the posterior wall of the bladder, produced presumably by the end of the pencil. The organ was filled with clotted blood.

CASE V, aged fifty years, was admitted into Troy Hospital, complaining of difficulty in urination, and the existence of a fistula in the perineum through which urine escaped. A sound was introduced and after passing a moderately tight stricture a calculus was encountered. This was removed with urethral forceps, and the reintroduction of the sound revealed the fact that the canal was blocked with débris which could not be entirely removed. With the object of both removing the débris and healing the fistula, perineal section was performed, and a spoonful or more of phosphatic débris was taken away. The bladder was free from stone, although chronic cystitis was present. After curetting the fistulous tract, the bladder was irrigated and the wound was packed. The catheter was left in place for a day or two; then, by applying a compress to his perineum the patient passed most of his urine per meatus. The fistula gradually and completely closed.

All of the foregoing cases required a perineal operation. We encounter cases, however, in which it is not necessary to do any operation, as the point of rupture may close quickly without symptoms. As already stated, if the rupture is in the spongy or prostatic portion, there is not, as a rule, any extravasation. This is illustrated by the following:

CASE VI.—This man introduced a hair-pin into his urethra to dilate a stricture; the hair-pin slipped in and disappeared. About a week later the ends of the pin appeared, one on each side of the meatus. He tied them together with thread to prevent them from slipping back. When I saw him I snipped off one end, and unhooked the other. No symptoms of rupture were present, although the body had made two openings through the urethral wall an inch and a half from the meatus.

CASE VII is a peculiar one because the urethra was ruptured by a foreign body in the rectum. The patient, aged about forty, about five day previously to my seeing him in consultation had swallowed an artificial tooth-plate. He was given proper diet and kept quiet for four days, when he was attacked with severe urethral hemorrhage. His attendant examined his rectum, found the tooth-plate, and with a little difficulty removed it. The hemorrhage from the urethra continued, no blood, however, escaping from or into the rectum. Neither did any find its way into the bladder, as the urine passed after the first instant was clear. We passed a large soft catheter, which controlled the bleeding. There was no extravasation. The catheter was left in place for forty-eight hours, although once in the interval it was expelled by the patient, with a return of the hemorrhage. Reintroduction of the catheter once more stopped this. The tooth-plate probably had punctured the urethra by one of its projecting points, making a valve-like slit, which prevented the blood from passing toward the rectum, and also preserved the parts from extravasation.

The prognosis as to life in rupture of the urethra depends, as we have seen in the foregoing cases, upon the condition of the patient at the time of the operation. If several days have elapsed since the injury, with little or no urine passing, and with extravasation, the chances are against recovery. On the other hand, with slight injury, some water passing, and with little or no extravasation, the patient should recover in every instance, as well as in those more severe cases that have been seen and operated upon within a few hours after the accident.

The causes of urethral rupture, therefore, may be internal, external, or through some other organ.

The symptoms are difficulty in urination or retention; pain; swelling in the perineum; hemorrhage; dribbling of urine through the external wound.

If the cause be a foreign body, it should be removed, by the meatus if possible.

If there is no swelling in the perineum, and if urine flows freely through the meatus, allow nature to take its course, watching closely for any further symptoms.

If swelling exists in the perineum, with evidence of extravasation, perineal section should be done at once.

Care must be taken to keep the wound and the bladder as aseptic as possible.

Supporting and antipyretic treatment should be vigorously employed.

The prognosis should be guarded.

Care should be given as regards the caliber of the urethra for several weeks afterward.

CLINICAL MEMORANDUM.

THE LOWEST LIMIT OF PELVIC CONTRACTION ADMITTING OF SYMPHYSIOTOMY.

By BARTON COOKE HIRST, M.D.,
PROFESSOR OF OBSTETRICS, UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, PA.

An impression prevails that symphysiotomy is the proper operative treatment for labor obstructed by a moderate degree of contraction in the pelvis, in which the other alternatives are the induction of premature labor and craniotomy. This view was expressed without contradiction at a recent meeting of a prominent medical society at which the operation was the sole topic of discussion. Increasing experience, however, demonstrates that symphysiotomy is to be depended upon in the case of a pelvis symmetrically contracted, that a few months ago would have been thought quite impassable for a living child, even though the symphysis were cut. Leopold has recently delivered in this way a woman with a pelvic conjugate of only 6 cm., and more than a month ago in the Philadelphia Hospital I delivered without difficulty a rhachitic dwarf, a primipara, 4½ feet high, whose conjugate was, I think, very little if at all over 65 mm. The diagonal was a scant 9 cm., but the conjugato-symphyseal angle was so increased that 2¼ cm. was, in my judgment, a sum scarcely sufficient for the subtraction. To be on the safe side I induced labor two weeks before term; then dilated the cervix, performed version after opening the symphysis, and extracted the child in a few minutes. It weighed 6 pounds, 4 ounces. The head-measurements were: Bi-temporal, 8 cm.; bi-parietal, 9 cm.; occipito-frontal, 11½ cm.; occipito-frontal circumference, 33½ cm. The woman had an absolutely afebrile convalescence and the child is thriving.

The combination of delivery before term and symphysiotomy will give us entire control over any grade of symmetrically contracted pelvis that we are likely to see in this country, and whenever possible the two should be combined. In a very large experience with the induction of labor from two to four weeks before term I have found the mortality for the children no greater than in delivery at full maturity, whereas the slight diminution in head-diameters and the compressibility make a vast difference in the ease of delivery. Another, and a very great advantage in the induction of labor when symphysiotomy is contemplated is the fact that a convenient hour can be selected by the operator for the delivery, and all preparations can be made for the appointed time, as in an abdominal section. The plan adopted in the case here reported, and always followed by me if practicable, was as follows: Early in the morning a bougie is inserted and an ounce of glycerin injected alongside of it. Twenty-four hours later the lower abdomen is cleaned and shaved. By this time, if the pelvis is so contracted that the head cannot enter the inlet, the cervix will be softened but scarcely at all dilated. The cervical canal is then dilated with three sizes of water-bags, the largest twice the size of the largest Barnes's bag, each left in for about an hour. This is most conviently done by an assistant. At about the time that the artificial dilatation is completed the operator arrives prepared to operate and deliver as soon as the patient is anesthetized, the vagina is disinfected, and the instruments are sterilized.

MEDICAL PROGRESS.

Nervous Disorders in Tuberculous Patients.—In a study of the nervous disorders of tuberculous patients, Weill (*Revue de Médecine*, 1893, No. 6, p. 450) has found that in about 40 per cent. of cases there exists profound hyperesthesia—muscular, articular, and osseous. This hyperesthesia, apart from spontaneous pain, may be distributed over the whole body, but always predominates upon one or the other side. It is generally situated upon the neck, the trunk, and the roots of the extremities. The opposite side of the body may be anesthetic or hyperesthetic. Often there is also concentric and regular limitation of the visual field, unilateral or bilateral. Rarely there is muscular weakness. Muscular hyperesthesia is the most constant, the first to appear, and the last to disappear. Once present, these nervous disorders attain their maximum intensity in from a few days to two months. Rarely do they persist longer than three months. They disappear slowly and progressively in the course of a few weeks. Occasionally, they disappear rapidly. These nervous disorders have no relation, either as to intensity or as to distribution, with the seat, extent, and gravity of the pulmonary lesion. They generally appear in the early months of the tuberculous process; but once present, they seem to pursue an independent course. They occur alike in benign and in grave forms of tuberculosis. Sometimes they pursue a course opposite to that of the pulmonary phenomena, exacerbating when these decline, and *vice versa*. In a large number of cases, however, the course of the two manifestations is parallel. An intimate relation exists between this syndrome of nervous symptoms and that form of pulmonary tuberculosis attended with erethism, spasmodic cough, attacks of oppression, vomiting, and palpitation. These symptoms, by their character, suggest the stigmata of hysteria. In none of the twenty cases studied, however, was there a history of neurotic heredity, of convulsive attack, or of mental peculiarity. The condition must be considered as a symptomatic hysteriform condition. The phenomena are thought not to depend upon the action of the bacillus of tuberculosis upon the nervous centers, nor upon microbic intoxication. They must be regarded as manifestations of a centripetal irritation, of which the point of departure is constituted by the sensitive nerves of the bronchi and lungs.

Successful Excision of Hydrencephalocele.—CHARLES H. MAYO (*Annals of Surgery*, vol. xviii, No. 1, p. 26) has reported the case of an infant, a year and a half old, who presented a spherical pulsatile tumor, of the size of a small orange, projecting centrally from the occipital region, and which had been present from birth. The prominence was so tender that anesthesia was required to permit of the examination. The crest of the tumor was white and glistening, and apparently very thin, with a few veins coursing over its surface. The sides were evidently much better protected. At the right base there was a considerable thickening, evidently connected in the past with the cranial contents through a lateral fissure from the central opening. Operation having been decided upon, two scalp flaps were dissected from the sides of the tumor, and the dura mater was freed to the bony opening, which led inward and slightly to the right, and probably communicated with the right ventricle. The sac was opened, and an ounce of apparently normal cerebro-spinal fluid escaped. The sac-wall was composed of dura mater, and near the base, spreading out thinly on the sides, was evident atrophied cerebral tissue. The neck of the mass was ligated with heavy catgut, the entire sac cut away, the tissues around the stump securely fixed over it by buried sutures, the two flaps sutured in apposition, and a dry dressing applied. During the application of the dressing the child vomited, and the increase of intra-cranial pressure caused a pronounced left-sided spasm, lasting several minutes. Five grains of calomel were administered, with rapid effect, and the child made an uneventful recovery. The child was dismissed at the end of two weeks, the wound firmly united, and with no appreciable pulsation at the seat of operation.

Convulsive Tic.—At a recent meeting of the New York Neurological Society, DR. J. F. TERRIBERRY presented a male, thirty-nine years old, who, eight or nine years before, had noticed slight twitching of the muscles about the left eye, which gradually became more marked and extended to the muscles of the cheek, so that in a short time all of the muscles of the left side of the face were involved in the spasm. The movements occurred in paroxysms, separated by intervals of an hour or two, and it was said that they took place during sleep. They were aggravated by talking and by emotional excitement. Careful examination failed to reveal any organic trouble, either central or peripheral, in the course of the seventh nerve that could act as a cause. There was, however, decided nasal obstruction on the left side, which was removed. Some errors of vision were also discovered and corrected. The spasm of the facial muscles, however, was in no way affected by the correction of these defects. The operation of stretching the facial nerve was advised, and was performed, the nerve being exposed by an incision behind the ear. A weak faradic current greatly facilitated finding the nerve. When located, it was picked up with a blunt hook and stretched, the force employed being from four to seven pounds. The immediate result of the operation was, as had been expected, complete paralysis of the muscles of the left side of the face. There was no effect upon the hearing, taste, or the palatine muscles, showing that the effects of the traction were not felt centrally. Subsequently, a gradual return of voluntary control of the facial muscles was noted, and this steadily increased. There was no return of the spasm after the operation.

Hemorrhagic Infarct of the Testicle.—ENGLISCH (*Wiener medicin. Blätter*, 1893, No. 23, p. 303) reports three cases of hemorrhagic infarct of the testicle, and refers to three others recorded in the literature. The condition is characterized by sudden swelling of the testicle, and in less degree of the epididymis, with the formation of a firm band in the course of the spermatic cord, without assignable cause; rapid inflammation of the scrotum; general prostration; nausea, vomiting, and sometimes symptoms suggestive of peritonitis; acute hydrocele of slight degree; distention and thrombosis of the veins; inflammatory extension to adjacent structures. The temperature remains elevated for two or three days. Anatomically, the veins are found distended with blood, while groups of lymphoid cells are present in the interstitial tissue, without inflammatory changes. Blood is extravasated between the seminiferous tubules, and there are deposits of pigment. The epithelium of the tubules is cloudy and fatty. In the further course of events the testicle undergoes atrophy. In most cases no cause for the condition can be determined, but from the youth of the patients, the thinness of the walls of the veins would seem to be a predisposing factor. An infective influence is not to be entirely excluded. The treatment consists at first in active antiphlogosis. If the symptoms fail to yield, skin, vaginal tunic, and testicle should be incised down to the body of Highmore, and the gangrenous tissues be permitted to be thrown off. Only in case of profuse suppuration should the testicle be entirely removed.

Foreign Body in the Ear for Twenty-one Years.—PRITCHARD (*Lancet*, No. 3641, p. 1383) has reported the case of a married woman suffering from acute follicular tonsillitis, which readily yielded to treatment. Interrogated as to whether she had had any ear-trouble previously, the woman stated that for a number of years she had suffered from neuralgic pain and a sensation of a foreign body in the auditory canal. It was recalled that during childhood the woman had placed a pea in the ear, which was not removed. The application of warm oil and syringing with warm water removed considerable wax and disclosed the presence of a dark, roundish body adhering to the posterior wall of the canal. Syringing failing to remove this body, a fine silver-wire snare was carefully passed beyond it and the body was dislodged and on examination proved to be an ordinary pea. It was considerably shrivelled and in part covered with epidermis.

A New Method of Auscultatory Percussion.—SMITH (*Medical Record*, June 24, 1893, p. 777) reports the employment of a new form of auscultatory percussion, by means of which he believes shades of differential dulness may sometimes be detected that would otherwise escape observation. The small extremity of the binaural stethoscope is held between the patient's teeth while the lips are closed around it and the nostrils are compressed by the fingers. The results obtained do not differ in kind from those obtained by percussion in the ordinary way, but the intensity is greater.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including Postage in North America.

Per Annum, in Advance . . . . . $4.00.

Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, AUGUST 5, 1893.

THE DISORGANIZATION OF THE AMERICAN MEDICAL PROFESSION.

"Did you attend the meeting of the American Medical Association at Milwaukee?" was asked of a physician a few days ago. "O, no! I do not train with that sort of a crowd," was the unexpected reply. This attitude of mind was hopeless, and the suggested Dundreary proverb concerning the kind of a bird that "flocks all alone by himself," was useless.

But this attitude of mind is one that two bodies have to look to a bit. The medical profession, as a whole, will sooner or later give it a sharp answer, and, whether this answer be spontaneous or compelled, another somewhat important body, called "the body politic," will have a very decisive word to say about it.

The disease is evident; it is a rebellion of the members against the whole body; it is an exaggeration of individualism, a democracy so rampant that factionalism has become easier than union. We are, it is true, in the full-tide of political democracy, but we have not yet reached socialism or anarchy. We still abide politically in representative government and (at least since 1861) in the rule of the majority. But in medicine we seem to think no organization necessary, and that professional individualism, factionalism, or anarchy is our natural state. There is even a touch of pride in flocking by oneself or with a half-dozen like-minded self-flatterers.

Have we then no common duty, such a duty as can only be performed by the profession acting and speaking as a whole? If not, then of course there is no logical or valid answer to individualism. But to ask the question is to answer it with a ringing "Yes, we have such duties, and we are disloyal if we say we have not!"

But viewed simply as a professional matter, a little family affair with which, *pro tempore*, it may be admitted the lay world has no concern, what about this indifference to organization and this refusal of corporate duty? It is plainly a question of self *vs.* the medical profession; it is, frankly, nothing more than professional rebellion.

It is smiled over and talked about as an open secret that the formation of so many select and membership-limited societies of specialists has been motived by other reasons than dissatisfaction with the American Medical Association. It is said that they are not to be viewed as corporate protests against the "politics" and "the methods" of that or indeed of any possible general organization, but that they are attempts to divide the consultation practice of the country among the limited number of fortunate members. This may be untrue. It is not for us to decide, but the action certainly permits the suspicion to arise, and the way to allay it is not to continue the contemptuous indifference to, and utter neglect of, some common organization.

It may also be noted that there is no evil more evident, no evil more universally deplored by rational medicine than the evil of medical sectarianism. But what bouffe logic, to complain of the homeopathic, eclectic, or Kneipe crank and sectarian, while scorning general organization and manufacturing factions and special limited societies, even within the regular profession. So long as the profession does not shake itself together and present to the public the spectacle of a united body of men agreed upon all the essentials of medical practice, just so long will that profession not command the respect of the world, and just so long will it be unable to accomplish its proper and destined work. To-day we are powerless to cause medical schools to be conducted for the sake of medicine instead of for the sake of the proprietors and professors; we are powerless to crush the hideous "patent" and proprietary medicine business; powerless to get "medical" news-

papers conducted for medicine instead of for the advertiser; powerless to bring about the nationalization of health; powerless to prevent the needless and useless one-fourth of all deaths and the one-half or more of the sickness that is such an enormous tax on the commonwealth and crippler of all social energy. And why this powerlessness? Simply because of medical sectarianism, professional disorganization, and anarchy.

There are numberless reasons that might be brought against the individualist and his neglect of professional organization. Sooner or later the common sense, or the sense that should be common, of the mass of physicians will recognize the fact that there is or must be such a thing as professional interests and duties, and that members of the profession must be held to an acknowledgment of them. Then will there be a quick ending of the factionalist and egotist. In every civilized country of Europe there is such organization and accountability. Even barbarous Russia regulates and stigmatizes the trade in patent medicine that free and civilized America sends to her in shiploads!

It was the witty saying of a wise man that democracy is only making pi, and certainly medical democracy is the absurdest of pi-making. Professional self-interest and the public interest stare at us from every aspect of life and work. There is no intelligence or corporate strength in this disunion. It is our duty to unite and to encourage *esprit de corps* by organization. Factionalism is an *esprit de corpse*, if the bad pun may be pardoned, and professional rebellion must be stigmatized, if not punished.

Considered simply as the largest medical organization in the United States, the American Medical Association offers the most suitable and the most probable gravitational center to which must gather the subordinate elements and groups. If not to your liking, it is not very liable to become more so by your non-membership. Parties, whether political or medical, are not mended by letting them alone. In every large organization thousands of minor differences and individual preferences must be sacrificed. The need of some organization is so great that longer to delay it is vanity and selfishness and whimsicality. There is slowly arising a general medical consciousness—unseen or scorned by the politician and anarchist—a spirit of centralization, a recognition of the duty of unity, nay, of the self-interest of unity. It will be well to reckon with this spirit, because its rule is as inevitable as its coming. There must be an end of this "flocking all by oneself," this cliqueism, coterie-forming, and limitless pi-making. This attitude of everlasting criticism by the disgruntled is silly and pig-headed. An aroused profession must sweep it aside, or else an aroused public sentiment will sweep an unworthy profession aside. There is even now a plain intimation of such a public condemnation of us in the fact that preventive medicine—the coming greater part of all medicine—is willy-nilly being taken out of the hands of physicians, and is being cultivated by the non-medical scientist. If this shall in fact and completely come about, it will be our own fault, a plain case of *felo de se*.

The American medical profession has one pre-eminent and imperative duty before it, to which all other interests and duties must be sacrificed, and that is the duty to organize.

BUTTER.

A CIRCULAR, entitled "Nostrums for Butter-making," recently issued by the U. S. Department of Agriculture, gives an interesting account of attempts to deceive the public by the sale of preparations purporting to increase the yield of butter from a given amount of milk. The officers of the department express, naturally, some dissatisfaction at the readiness with which farmers have taken up with the fraud, not only because it must appear that the use of any such preparation is dishonest; but, with the information that has been liberally afforded by the bulletins of the department, any intelligent agriculturist can learn that no more butter-fat can be obtained from milk than exists in it. It appears from the circular that most of these preparations are arrant humbugs. One form, widely advertised under the name of "black pepsin," varies in composition, some samples consisting of common salt, annatto, and a little rennet, while others are mixtures of pepsin and sugar.

It is worthy of note that in the extended discussion of food-adulteration of late years, butter has not received much attention from sanitarians. Milk, alcoholic beverages, and baking powders have caused the outlay of much breath and printers' ink, but even the enormous development of the oleomargarin industry has been met by opposition from commercial rather than from sanitary interests. The ears of health officers have remained dull to farmers' recitals of the evils that attend the use of

substitute butter. It is true that most repressive enactments relating to this subject have either in the title or preamble assumed an intention to protect the public health, but this is merely a legislative way of putting things to avoid conflicts with court-decisions.

This indifference need not be a matter for alarm, for while oleomargarin is not a perfect substitute for butter, and may never entirely replace it, it is, as now manufactured, apparently not unwholesome, and, therefore, not an object of sanitary restriction.

A more serious matter is the skilful adulteration of genuine butter, by the use of some of the "nostrums" noted, or possibly by methods not yet known to the authorities. The result is the production of a commercial article containing an excess of water, sometimes over 40 per cent., while good butter will not contain over 10. Such an article is spongy, and becomes rancid readily. It is, of course, a great fraud on the consumer. Butter of this kind is often sold in Philadelphia, especially among the poorer population. Indeed, there seems to be an organized system for its manufacture and sale. It will, doubtless, be difficult to stop such a practice. The product cannot be considered unwholesome, except by an extreme construction of the term, and as water is a normal ingredient of commercial butter, the issue must be made on the percentage present. No legal standard of percentage exists in this State, and it might be very difficult to set one up in an individual case to the satisfaction of a jury. It is, however, of some interest to know that systematic frand is occurring frequently with regard to an extensive and important food-product.

If efforts are made to secure a general law against food adulteration at the next Legislature, it will be well for those interested to bear in mind that the substitution by oleomargarin is not the only fraud that is practised by the purveyor of butter, and to provide for a minimum percentage of permissible fat.

ON A CERTAIN LACK OF HUMOR IN PHYSICIANS.

Physicians may undoubtedly be pardoned for it, but they surely have a natural or acquired deficiency of the sense of humor. Their right to pardon comes from the tremendous seriousness of their daily work; they may not even smile at the unconscious jokes of their patients, except after they and their "guitars in their noses" have left the office. "It's awful to have the nerves, doctor," and it's awful likewise *not* to have 'em. Some years ago a medical humorist began the compilation of an encyclopedia of medical wit and humor and solicited contributions from all physicians. The contributions came in huge packages, but they were neither witty nor humorous —they were simply—not to be printed. The would-be author-editor never smiled afterward. It was a sad case of pseudo-cyesis.

Another proof of this thesis has lately come to our notice. Remarking, with much despondency of heart, that physicians as well as "the vulgar herd" like to handle secret proprietary remedies and believe in outrageous claims and certificates of impossible cures, a humorist spent considerable money in advertising in "reputable medical journals" a series of preparations, trade-marked and patented, of the most astonishing qualities and powers. Certificates from pompous magnates, with titles of surpassing length as tails to their names, were appended; and the whole affair was set forth with the customary effrontery in the remarkable scientific jargon of the professional advertisement-writer. The actual advertisements are before us as we write.

For the anti-vaccinationists and the aristocratic, "Jennerine" possessed a charm; it was of spontaneous production in a blooded cow of long pedigree, but for many generations had been carried through the human royal family of England, acquiring thereby great intensity and nobility. Transmission of the virus and inoculation could also be effected by telegraph "over many miles of wire."

Of "Pasteurine," the universal microbicide, the formula was published, though the name was trade-marked, and "other dealers are warned, etc." And this is the formula:

> Nitrogen, one volume.
> Carbonic acid gas, pure anhydrated, two volumes.
> Permanganate of potash, two parts by weight.
> Pure oxygen, without admixture, one volume.
> Pure carbon in crystalline form, one part by weight.

"Consumptine" was guaranteed a sure cure for consumption. As regards Croupine, the physician required especial teaching and drilling in its application, to prevent the digestion of the membrane of the patient's throat while being swallowed. Its price was $7.50 per ounce, "very reasonable in consideration of the results obtained." "Dyspepsine" and "Cancerine" were guaranteed of absolutely

unfailing power. "Ostrichine" enabled one to eat mince pie and railroad sandwiches with impunity. ("We raise our own ostriches.")

"Brainerine" needed only its name to recommend it. "Brains are scarce just now," says the advertisement, "and for this reason our supply, for a few years, will be limited. Physicians requiring this article for their personal needs or those of their patients, will please apply with subscription at once."

And now for the promised proof of professional lack of humor: To the address of the "Nineteenth Century Therapeutical Company," from every part of the United States, came thousands of serious letters from physicians—literally thousands—requesting samples, ordering supplies, and making inquiries as to the applicability of these remedies to ailments described in detail!

EDITORIAL COMMENTS.

The Supplying of Germ-free Milk.—It is one of the strange things that the first attempt to supply under scientific supervision a clean, pure milk, free from germs, is yet to be made. That a food so universally used, so necessary, and so easily becoming not only unhealthful, but the very carrier of multiform disease, should be left to the carelessness and cupidity of uneducated men, is a fact almost beyond belief. The cows and the men who milk them are almost always filthy, and are often diseased. At Hightstown, N. J., for example, eighteen cases of diphtheria were recently traced to one dairy, where a boy with the disease was employed to wash the milk-cans. The germs of typhoid fever, of scarlet fever, and of tuberculosis are, as is well known, carried in milk.

At Caldwell, N. J., important experiments are about to be made to prove that milk may be produced under conditions that will guarantee its purity. The experiments are to be carried out under the supervision of a medical commission, with which are associated chemists, bacteriologists, and veterinary surgeons. All requirements may be carried out by a farmer of ordinary intelligence, with medical and veterinary supervision. It is estimated that certified milk can be delivered for twelve cents a quart.

The plan outlined includes three general requirements:

1. That physicians give their practical support to an effort conducted by a commission selected from their own number, who shall endeavor to bring to the city a supply of milk, produced under such regulations that purity shall be assured.

2. That approved and trustworthy dairymen, possessing honor, financial ability, and dairy-facilities, shall be induced by reason of promised medical support and the increased price of their milk, to conduct their dairies, collect and handle their products, in conformity with a code of requirements made by the aforesaid medical commission, and imposed by them in due legal form.

The contract shall include the sureties for its fulfilment; the location and character of the land; the construction of buildings; the water-supply; the surroundings; the health and breed of the dairy-stock; the housing and care of the cows; the feeding; the collection and handling of the milk; its cooling and preparation for shipment; the bottling and transportation, together with the minor details of delivery.

3. That the commission shall carry on its work without pecuniary compensation. Its duties shall be: First, to establish correct clinical standards of purity for cows' milk. Second, to be responsible for a periodic and personal inspection of the dairy or dairies under its patronage. Third, to provide for bi-monthly expert examinations of the dairy stock by a competent and approved veterinarian. The milk produced shall be subjected to chemical analysis and to bacteriologic tests, made under the direction of the commission at such times as in its judgment are desirable.

The veterinary surgeon, chemist, and bacteriologist shall be selected by the commission, and when so requested, either periodically or otherwise, they shall render their reports in writing. The expense of all examinations should be defrayed by the dairyman, as he is the only party gaining a pecuniary advantage. These expert reports, although designed for certificates, may also be used for the information of the medical fraternity in the localities where the milk is sold.

After receiving these reports, the commission should send a certified copy of the same to the owner or agents of the dairy or dairies under its supervision. Duplicate printed copies, bearing the signatures of the experts and the names of the commission, should be issued by the dairymen, at such times as may be agreed upon, and the circulation should, for obvious reasons, be limited to physicians.

The milk thus produced should be known as certified milk; should be sealed in separate quart-containers, and bear the name of the producer, together with the date of milking. The milk, being designed especially for clinical purposes, should be subject to the following restrictions in its sale, namely, that when at any time the demand is greater than the supply, and the milk is required by a physician, either for infant-feeding or the diet of the sick, it should be agreed that the physician or his patient shall be a preferred purchaser.

The agreement required of dairymen entering into contract binds them to the conduct of dairies in conformity with specified requirements, including the costs of chemic and bacteriologic examinations; inspection at least bi-monthly; subjects the location of lands, the construction of buildings, the water-supply and surroundings to the supervision of the commission. It provides conditions for the selection of the dairy-stock, excluding from the herd used for producing certified milk "any animal bred through close consanguinity; any animal that was not, as a heifer, kept sterile during its first twenty-seven months; any phenomenal milker, unless glandular disease or tubercle has first been excluded by a competent observer." The housing and care of stock, feeding, collection and handling of milk, preparation for shipment, the bottling, transportation, and delivery are all governed by rules specified in the contract, the violation of which is subject to penalty.

The commission has freed itself from all chance of self-interest in any of the experiments to be made. Members thereof are forbidden to act as experts, or being in any way interested in the matter, other than for professional purposes.

Adaptation of Cow's Milk.—Soxhlet has recently issued a pamphlet entitled *The Chemical Differences Between Cow's Milk and Human Milk, and the Means of Equalizing Them.*" The author, although perhaps not known to many clinicians, is an eminent authority in analytic chemistry, and, as translations and abstracts of his

pamphlet are beginning to appear in the journals, it will be well to note that there are some errors in it. Soxhlet proposed to make cow's milk of the same dietetic value for infants as mother's milk, by adding half the volume of a 12.3 per cent. solution of milk-sugar. This gives, he states, a percentage of casein equal to that of human milk, while the milk-sugar equals nearly 10 per cent., the excess over that usually in human milk being intended to compensate for the reduction of fat by dilution. The author states, upon the authority of another investigator, that milk-sugar may replace fat in the proportion of 24 to 1. As a matter of fact, the figures given are erroneous. To obtain a solution containing 9.4 per cent. of milk-sugar it will be necessary to add a half-volume of a solution containing over 19 per cent.—a solution difficult to prepare. Soxhlet's formula will only give about 7.5 per cent. of sugar, while the fat will be reduced considerably. He further bases his formula upon the view that cow's milk is of constant composition, a view that is clearly untenable in the light of thousands of analyses now on record. The employment of cream for preparing imitation human milk is deprecated on the ground that there is no ready method of determining the amount of fat, a position which is also untenable, as rapid and accurate processes available to unskilled workers are now known. As an essay by so distinguished an authority will be likely to receive unquestioned acceptance by many, it seems necessary to note its defects.

The Etiology of Asiatic Cholera.—The doctrine of the specificity of the comma-bacillus in the etiology of cholera has been especially opposed by the Munich school. At first another organism (the bacillus neapolitanus of Emmerich and Buchner) was credited with being the causative factor. When the correctness of this claim was disproved, great importance was attached to local and individual conditions, the comma-bacillus being conceded only an incidental relation. Now that it is admitted that there can be no cholera without the comma-bacillus, the attempt is being made to prove that the symptoms are not dependent upon influences that are peculiar to the comma-bacillus. Emmerich and Tsuboi (*Münchener medicin. Wochenschr.*, Nos. 25 and 26, 1893) endeavor to demonstrate that the clinical picture of Asiatic cholera is the result of an intoxication by nitrites generated by the cholera-bacilli. We are quite willing to admit that nitrite-intoxication may be a factor in the production of the symptoms, but we are scarcely ready to believe that these are solely dependent upon this influence. We have not a little yet to learn concerning the etiology of cholera, but at this stage it would be exceedingly difficult to ignore, not to say disprove, the specific influence of the comma-bacillus, however complex this relation may be.

The Iowa State Board of Medical Examiners is determined to break up sham medical colleges and sham medical education if possible. No medical college will hereafter be recognized by the Board as in good standing that does not require as a condition of graduation "four graded courses of lectures of not less than six months each—no two of which said courses being in the same calendar year." Colleges not coming up to the minimum requirements (preliminary examinations, four years' study, attendance at quizzes, examinations, etc.) are notified that the Board certificates will not be granted to their graduates. The Eclectic College is making a fight against the ruling in the courts; but as an indirect result of the controversy it is found that it has no charter right to confer a degree, and that according to its charter it is only authorized to organize and teach "for pecuniary profit."

REVIEWS.

Saint Bartholomew's Hospital Reports. Edited by W. S. Church, M.D., and W. J. Walsham, F.R.C.S. Vol. XXVIII. With Statistical Tables of the Patients under Treatment in the Wards of St. Bartholomew's Hospital during 1891. By the Medical Registrar, J. A. Ormerod (Oxon.), F.R.C.P., and the Surgical Registrars, Anthony A. Bowlby, F.R.C.S., and C. B. Lockwood, F.R.C.S. Pp. 370. London: Smith, Elder & Co., 1892.

This report contains thirty papers, of varying degrees of interest, merit, and originality. We can only make reference to some of the more important matters. Mr. Howard Marsh points out the exceeding difficulty sometimes encountered in the differential diagnosis of new-growths and inflammatory enlargements of bone. Mr. Harrison Cripps, in speaking of hernia as a complication of abdominal incision, says that "One of the causes of this is allowing the patient to get up too soon without adequate support to the abdomen. All scar-tissue, in its earlier days, is comparatively soft, and will slowly yield to anything like constant pressure; on the other hand, after a while, it becomes of the firmest and least yielding structures in the body. A carefully made abdominal belt will be sufficient protection after the first few months; but for the first three months, if the incision has been of any length, it is most desirable that the patient should apply three or four turns of thin roller bandage, five inches wide, around the abdomen firmly, on rising in the morning. The patient should be enjoined to keep the recumbent posture as much as possible, and avoid any exercise that causes undue action of the abdominal muscles." Mr. Arthur Maude contributes a note on the application of Leiter's tubes to the precordium in the treatment of exophthalmic goiter. He uses a large-sized rectangular coil, at first for twenty or thirty minutes, morning and evening, the time of application being gradually increased until the coil is worn for some hours daily. Many months are necessary for anything like permanent improvement. Nephritis is a possible danger from the treatment, which should not be employed if albuminuria be present. In all cases the urine should be periodically examined. Dr. Andrew Haig makes the proposition that the contraction of the vessels in Raynaud's disease is a result of the presence of uric acid in the circulation. Dr. T. Clay Shawe argues that in certain cases of insanity the performance of trephinig may be a justifiable procedure, and reports an illustrative case. Dr. Vincent D. Harris records an analysis of forty-one cases of intra-thoracic growths in St. Bartholomew's Hospital, from 1882–91, and also the epitomized notes of nineteen cases of a similar kind in the City of London Hospital for Diseases of the Chest, Victoria Park, during ten

years. Mr. W. McAdam Eccles makes an interesting analysis of twenty-eight cases of intussusception. Nine cases of intestinal obstruction are treated of by Mr. F. W. Tuncliffe, to which are added some remarks by Mr. Bruce Clarke. Dr. J. A. Ormerod reports four cases of acute ascending paralysis. Mr. Arthur J. Hall reports a case of hepatic cirrhosis in a girl eleven years old. Mr. E. Cautley details a bacteriologic study of the etiology of croupous pneumonia. He raises the question whether the presence of microörganisms in the lung in pneumonia may not in most cases be regarded as a sequel, and concludes that if the disease is dependent upon the presence of microörganisms, no one single species is present in every case. Dr. G. G. Morrice calls attention to the occurrence of suppression of urine in the course of diphtheria. Mr. F. E. Batten reports three cases of "progressive muscular atrophy associated with loss of sensation to heat and cold," in one of which post-mortem examination disclosed the presence of a cavity occupying the central canal of the spinal cord. Dr. H. Lewis Jones contributes interesting notes from the Electrical Department, in which he considers the management of the apparatus and the treatment of the cases. Sir Dyce Duckworth and Dr. H. H. Tooth report two cases of general spastic rigidity of unusual type, in which the explanation is ventured of a primary meningitis, followed by inflammation of the cortex and subsequent sclerosis. The volume concludes with a descriptive list, specimens added to the museum during the year 1892, and statistical tables for the year 1891.

A Text-book of the Theory and Practice of Medicine. By American Teachers. Edited by William Pepper, M.D., LL.D., Provost and Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania. In two volumes. Illustrated. Philadelphia: W. B. Saunders, 1893.

The list of authors of this latest addition to coöperative medical literature is certainly a good one. In the two volumes will be contributions by J. S. Billings, Francis Delafield, R. H. Fitz, James W. Holland, E. G. Janeway, Henry M. Lyman, William Osler, William Pepper, W. Gilman Thompson, W. H. Welch, James T. Whittaker, James C. Wilson, and Horatio C. Wood; in addition to whom, the editor acknowledges the assistance of Dr. F. A. Packard.

The work is likely to be well received, its teachings being those of the advanced schools of the day. All of the articles are well written, though some are better than others, especially in the matter of treatment. In this respect, we confess to much disappointment in the article on "Influenza" by the editor. While caution is suggested in the use of antipyretic drugs, such use in many cases is not only condoned but even advised—very bad advice, no matter how eminent the adviser. The two formulæ given, one for a pill of quinine, opium, digitalis, squill, and licorice; the other for a solution of morphine, quinine, and strychnine in phosphoric acid, glycerin, and water, are excellent examples of a polypharmacy that, in this disease above all others, should be avoided. The value of strychnine, ammonium preparations, and the terebinthinates is recognized, but hardly sufficiently emphasized. Salicin and its derivatives, and sodium benzoate, probably the most useful of all drugs except strychnine, are not mentioned; neither is the importance of securing free diuresis. It is true that the experienced practitioner does not need to be urged to look after all the secretions, but the student who will use this text-book does. We must also differ from the author as to any danger of increasing catarrhal complications by "hydrotherapy." If, however, he means to say that the cold bath is unnecessary and would in many cases be dangerous by abstracting necessary heat, we heartily agree with him. Indeed, we believe that part of the evil results of the coal-tar products is due to their depression of temperature.

The article on "Typhoid Fever," also by the editor, is excellent throughout. It is indeed one of the best condensed studies of the subject in the English language. We might differ from the author as to the utility of silver nitrate or the period at which alcohol is to be used. The recommendation of hydrotherapy is judicious, but we regret to see antipyrin given in never so small dosage. We are glad to see turpentine intelligently recommended.

Among the best articles are those on "Mental and Nervous Diseases," by H. C. Wood; while Osler writes of "Diseases of the Brain, the Muscles, and the Nerves," in his own rare style of brief inclusiveness. Billings's article on "Hygiene" is all that it ought to be, and its prominence in a text-book of practice is a bit of brilliant editorial work.

Whittaker contributes a series of articles on various acute infectious and parasitic diseases, and Thompson treats of syphilis, malaria, diphtheria, cholera, yellow fever. Detailed review is impracticable, but the articles as a whole are good, and can be confidently referred to by student and practitioner.

A Text-book of Medicine for Students and Practitioners. By Dr. Adolf Strümpell. Second American Edition, Translated by permission from the Second and Third and Thoroughly Revised from the Sixth German Edition, by Herman F. Vickery, A.B., M.D., and Phillip Coombs Knapp, A.M., M.D., with Editorial Notes by Frederick C. Shattuck, A.M., M.D. With 100 illustrations. New York: D. Appleton & Co., 1893.

Concise, full, and accurate; permeated with knowledge both theoretic and practical, Strümpell's text-book has won for itself a place in the front rank; and the additions made by the American editors enhance its value for American students and practitioners. We can select but a few points for comment. Accepting the current theories of infection, the author is by no means blind to possibilities outside of the prevailing doctrine. Thus, in discussing the etiology of enteric fever, while attributing the origin of the disease in every instance to invasion by typhoid-bacilli, he upholds the view of multiplicity of means of conveyance; and admits that individual predisposition is likewise necessary to the development of the disease. Attention is directed to the frequency of inhalation-pneumonia among the complications of enteric fever; but the existence of a croupous pneumonia dependent upon the typhoid-poison is likewise recognized; and due prominence is given to cases of "pneumo-typhoid" in which the early symptoms suggest pneumonia rather than enteric fever.

The treatment by cool bathing is recommended. We are glad to see hydrotherapy likewise advised in scarlet fever. The use of hydrogen dioxid for the throat and nose is not mentioned; yet we have come to look upon it as an essential element in the treatment not only of scarlatina but of all other diseases presenting similar local conditions. At the present time we turn with some interest to the chapter upon Cholera. The author warmly advocates opium, not only in the preliminary diarrhea, but later. Injection of hot saline solutions into the veins, enemata of tannin, and other measures of the kind are merely mentioned without expression of opinion. In the diagnosis of digestive disorders the author attaches great importance to examination of the gastric contents. In the treatment of perityphlitis opium is advised, and surgical means are not advocated by the author unless there is evident abscess. The editor, however, takes a more advanced view as to timely operation in appendicitis. There is a succinct chapter on Biliary Cirrhosis, but little help could be obtained in a doubtful case from the remarks on diagnosis. Even with the editor's additions, the remarks on pancreatic disease are more unsatisfactory than the obscurity of the subject warrants. The section upon Nervous Diseases is one of the best and most complete presentations of the subject for the general practitioner. The specialist may note omissions and differ in part from the views advanced. As an evidence of careful clinical study, we are glad to see that in the article on Exophthalmic Goiter the occasional association of angina pectoris and of spontaneous gangrene is noted. "Insufficiency of convergence" is given due prominence among ocular signs.

To conclude, we can only speak of the work of the author and of the translators and editor in the highest terms, and congratulate the English-reading profession upon the appreciation thereof which has led to the issue of a new edition in English.

Alcoholism and its Treatment. By J. E. Usher, M.D., Fellow of the Royal Geographical Society of London; formerly Surgeon Supt. and Medical Officer of Health to the Queensland Government. New York: G. P. Putnam's Sons. London: Baillière, Tindall & Cox, 1892.

This little work is evidently an effort on the part of its author to fill a place long vacant on the shelf of the physician's library. He very aptly starts out by stating: "Generalizing has been indulged in by a host of observers, but in very few instances can we find evidence in detail of the manifold changes existing in chronically diseased conditions."

It is very plain that there has existed a pretty general failure to recognize inebriety as a disease whose etiology, development, pathology, and treatment are as worthy of and as imperatively demand the most studious and methodical observation and treatment as have been given to typhoid fever, croupous pneumonia, or diphtheria. This lack of attention by the neurologist, alienist, and general practitioner has left the medical library almost barren in practical literature upon alcoholism. That which is available suffers from the fault of either being too general to be useful or too highly theoretic and scientific to be of any practical value to the general practitioner. Thus an inviting loophole has been left open, through which have crept unprincipled "Quacks," "Charlatans," and "Pretenders," to prey upon a most unfortunately afflicted portion of humanity.

Dr. Usher has energetically reopened this field in a style of English that is most interesting and impressive, and gives some valuable suggestions to those who have been disposed to look upon inebriety as more frequently a vice demanding the pleading of the pulpit than the ministrations of the physician. He disapproves of the indiscriminate, nay even the free giving of alcohol to children. "Keelyism" is unqualifiedly condemned as irregular and unworthy of even the slightest indorsement by any regular physician. The work deals with alcoholism in its medico-legal aspect, as well as in its clinical manifestations, with treatment and so forth, and is largely a compilation from well-known writers and authorities.

One is singularly impressed by the fact that in treating the legal phase of the subject the author quotes chiefly English jurists, but when he takes up the medical side of the question he quotes American authorities almost exclusively, thus leaving the reader to believe that in Great Britain inebriety is treated by courts of law, while in America it is treated by physicians.

A Handbook of Pathological Anatomy and Histology, with an Introductory Section on Post-mortem Examinations and Methods of Preserving and Examining Diseased Tissues. By Francis Delafield, M.D., LL.D., and T. Mitchell Prudden, M.D. New York: Wm. Wood & Co., 1892.

A book that has reached a fourth edition in a comparatively short time needs no extended review, especially when, as in the present instance, internal evidence manifests careful revision, bringing the subject-matter fully up to recent knowledge.

The preliminary chapters on post-mortem examinations and the examination of diseased tissues are essentially practical and useful, particularly the former. The discussion of pathologic technique is very brief, though, perhaps, sufficient for the uses of the general reader. Those desiring further knowledge will avail themselves of special treatises.

The body of the work is devoted to the discussion of general pathology, including the consideration of microorganisms and the various infections, and of the special pathology of the individual organs and tissues. There is also added a section "on the lesions found in general diseases, in poisoning, and in violent deaths," which, in a rigidly scientific treatise, would be unnecessary, from the fact that the contents must be merely a repetition of matter treated of in various places in the consideration of the different organs and tissues; but the practical usefulness of such summaries will commend them to the general practitioner. This practical or, if we may so term it, clinico-pathologic character of the book is a conspicuous and commendable feature throughout. We note, with regret, the absence of all reference to the pathology of the nasal chambers, the importance of which is commonly overlooked by the general medical man. Throughout the book the evidences of the individual and careful work of the authors is conspicuous,

especially in the chapters devoted to the lungs and kidneys, and, though we may not be disposed to agree on minor points, the general exposition of the pathology of the various organs seems accurate and reliable. The illustrations are all original and constitute not the least attractive feature of the work.

CLINICAL LECTURES ON ABDOMINAL HERNIA, CHIEFLY IN RELATION TO TREATMENT, INCLUDING THE RADICAL CURE. By WILLIAM H. BENNETT, F.R.C.S., Surgeon to St. George's Hospital (London), etc. With twelve diagrams. Small 8vo, pp. 225. London: Longmans, Green & Co., 1893.

THIS is a book of great practical value, on a subject which can never lose its interest to the surgeon. Of the eleven lectures contained in it, three were originally published in the pages of the *Lancet*, and many who have read them there will no doubt be glad to possess them in this more permanent form, with the additional material now presented.

The topics discussed are: The deceptive nature of the symptoms of strangulation in hernia; the occurrence of such symptoms in cases in which the hernial sac apparently contains neither omentum nor bowel; some peculiarities met with in the arrangement and shape of hernial sacs; some of the difficulties and dangers of attempts at reduction of hernia by manipulation; the management of damaged bowel in strangulated hernia; median abdominal section in the treatment of hernia; certain unfavorable symptoms occurring after the reduction of strangulated hernia, whether with or without operation; the radical cure of hernia. All of these matters are discussed by Mr. Bennett in a clear and forcible style, and, with the exception of the last named, are illustrated by graphically-told clinical histories.

Did space permit, we should gladly quote some passages from these pregnant pages. In regard to treatment, Mr. Bennett seems to us to be in the best sense conservative. For example, while he does not absolutely condemn the resection of gangrenous intestine in strangulated hernia, he takes the ground that "the coexistence of a condition of the gut hopeless enough to require resection, with a state of the patient which is good enough to justify the operation, must be very rare." We may also express our entire agreement with his views as to median abdominal section in the operative treatment of hernia. His statement of the objections to this procedure can hardly be controverted with success, even by its brilliant proposer and advocate.

This book does not pretend to be a treatise on hernia, but simply deals with points suggested by cases which presented themselves in the wards of one of the great London hospitals. We feel assured that no practical surgeon, giving it the careful reading which it deserves, will fail to find in it both interest and instruction. Its merits will be best appreciated by those whose own experience has been the widest.

SYSTEM OF DISEASES OF THE EAR, NOSE, AND THROAT. Edited by CHAS. H. BURNETT, A.M., M.D. Vol. I. 8vo, pp. 789. Philadelphia: J. B. Lippincott Co., 1893.

THIS work will be completed in two volumes. The first volume, dealing with diseases of the ear, nose, and naso-pharynx, is, on the whole, a creditable addition to literature. Naturally the various chapters by different authors are unequal, but all are meritorious. In many of them we find statements justly open to debate, such, for example, as the mistaken dicta concerning the importance and the methods of treatment of adenoid vegetations, which mar an otherwise excellent chapter by Dr. Seiss; but detailed criticism is impracticable. In this connection, however, we would emphasize the importance of doing operations in the naso-pharynx under guidance of rhinoscopy and not of touch. Perhaps the best single chapter is that by Dr. Major, of Montreal, on Lupus, Syphilis, Tuberculosis, Glanders, and Diphtheria of the Nose and Naso-pharynx. John N. Mackenzie, of Baltimore, contributes an admirable study of atrophic rhinitis. Seiler, of Philadelphia, attempts to establish a difference between grip and influenza. The article shows careful observation of cases, but inadequate critical grasp. It is, however, a useful addition to knowledge.

The editor contributes an article on "Chronic Purulent Otitis Media," marked by his well-known clearness of expression, richness of experience, and soundness of judgment. Other specially valuable articles are those by Dalby upon "Foreign Bodies and Osseous Growths in the External Auditory Canal;" by Bacon on "Diseases and Injuries of the Membrana Tympani;" by Colles on "The Middle Ear in Renal, Malarial, Syphilitic, Gouty, Rheumatic, and Dental Diseases;" by Jack on "Removal of the Stapes;" by Blake on "Mastoid Disease;" by Oliver on "Ocular Lesions in Aural Diseases;" and by MacCoy on the "Anatomy and Physiology of the Nose and Naso-pharynx."

This being—fortunately or otherwise—the era of systems and coöperative authorship, we predict for Burnett's system the large sale that it deserves.

TREATISE ON THE DISEASES OF WOMEN, FOR THE USE OF STUDENTS AND PRACTITIONERS. By ALEXANDER J. C. SKENE, M.D., Professor of Gynecology in the Long Island College Hospital, etc. Second edition, revised and enlarged, with 251 engravings and 9 plates in color. Pp. 968. New York: D. Appleton & Co., 1892.

IN the preface of the first edition of this work the author states: "This work was written for the purpose of bringing together the fully matured and essential facts in the science and art of gynecology, so arranged as to meet the requirements of the student of medicine, and be convenient to the practitioner for reference." The demand for a second edition has demonstrated how fully this purpose has been accomplished. The reader cannot fail to commend the conservatism and honesty of the author's opinions, and the care with which the material has been collected and arranged. The second edition contains new chapters on ectopic gestation, diseases and injuries of the ureters, and vesical hernia. The first of these subjects receives in this edition a careful exposition, the want of which was among the few defects of the former edition. The author's conservatism, however, in this very important branch scarcely meets the standard which recent investigations on this subject have demanded. His advocacy of electricity forms too prominent a contrast to the treatment of the surgical aspect of the subject.

The author's work in the positional disorders of the uterus and laceration of the perineum stands preëminent among the contributions to this subject. His discussion of the use of pessaries throws much light upon a subject which has suffered from the want of careful treatment, both pro and con.

The publishers deserve great credit for the illustrations and general style of the work.

The Surgery and Surgical Anatomy of the Ear. By Albert H. Tuttle, M.D., S.B. (Harv.). Pp. 96, with twenty-eight original illustrations. (Physician's Leisure Library.) Detroit: George S. Davis.

This little book contains twenty-eight excellent original photogravures of the surgical anatomy of the temporal bone, but a great many inexcusable mistakes in spelling throughout the work. Of the twenty-eight legends beneath the illustrations, *eighteen* contain *repeated* mistakes in the spelling of the names of the various parts of the temporal bone, as, for example, "processus cochleariformi" instead of processus cochlariformis, occurs eight times in the legends besides elsewhere in the booklet; in fact, it is not spelled correctly anywhere, so far as we have been able to discover. "Fenestra ovale" occurs seven times instead of "fenestra ovalis," and "sigmoides" five times instead of "sigmoideus." An author is not obliged to use Latin names, but when he does he ought to use correct ones.

Proper names are incorrectly spelled in many places; thus "Schrapnell" for Shrapnell (Fig. 23 and table of contents), "Hugierer" for Huguier (Figs. 9 and 10), "Wrenden" (p. 101) for Wreden, and "Boltey" (p. 101) for Botey, in the bibliography. The text includes a fair resumé of modern otology.

An Introduction to the Study of Diseases of the Skin. By P. H. Pye-Smith, M.D., F.R.S., Physician to Guy's Hospital. Pp. 408. Philadelphia: Lea Brothers & Co., 1893.

This excellent book, written by one fully conversant with the subject, both in theory and in practice, may be heartily commended to the practitioner, as well as to the student. The subject is handled from the standpoint of modern dermatology, and at the same time teaches that theories should not override facts. Conservatism of this character is always to be commended. The work possesses distinctive originality, which makes it both attractive and valuable. While it is not a large volume, and is modestly styled an "introduction," it really possesses more of intrinsic worth than many other more pretentious books. The views as to pathology and treatment are modern, and are quite up to date. The author is to be congratulated upon having written a sound and useful book.

Cholera: Its Causes, Symptoms, Pathology, and Treatment. By Roberts Bartholow, M.D., LL.D., Emeritus Professor of Materia Medica, General Therapeutics, and Hygiene in the Jefferson Medical College, of Philadelphia. 12mo, pp. 127. Philadelphia: Lea Brothers & Co., 1893.

Within the limits of this little volume Dr. Bartholow has made a faithful presentation of the modern conception of cholera, based upon personal experience in two epidemics and upon a voluminous literature. The subject is considered in five chapters. The first consists of a brief historic introduction, the second deals with the etiology, the third with the symptomatology, the fourth with the pathology and morbid anatomy, and the last with the treatment. The practical character of the work is indicated by the fact that nearly half of the volume is dedicated to a consideration of the subject of treatment, including methods of prevention, quarantine, disinfection, vaccination, and general medication. The appearance of the book is most timely and, coming from such an eminent authority, will commend itself as a safe and useful guide upon a most important subject.

NEWS ITEMS.

The Proposed Bill of the New York Academy of Medicine to Establish a National Health-Bureau.—As reported by the Committee of the Academy, the following is the proposal:

A Bill to establish within the Treasury Department a Bureau of Public Health.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled:

Section 1. That for the purposes of this Act the States and Territories of the United States be and are hereby grouped into districts, to be known as "the sanitary districts of the United States," as follows:

The Northern Sanitary District shall include the States of Illinois, Indiana, Iowa, Michigan, Minnesota, Ohio, Wisconsin.

The Northeastern Sanitary District shall include the States of Connecticut, Massachusetts, Maine, New Hampshire, New York, Rhode Island, Vermont.

The Northwestern Sanitary District shall include the States of Idaho, Montana, North Dakota, Oregon, Washington, and the Territory of Alaska.

The Eastern Sanitary District shall include the States of Delaware, Maryland, New Jersey, Pennsylvania, Virginia, West Virginia, and the District of Columbia.

The Western Sanitary District shall include the States of California, Nevada, Utah, and the Territory of Arizona.

The Southern Sanitary District shall include the States of Arkansas, Alabama, Kentucky, Louisiana, Missouri, Mississippi, and Tennessee.

The Southeastern Sanitary District shall include the State of Texas, and the Territories of Indian Territory, New Mexico, and Oklahoma.

The Central Sanitary District shall include the States of Colorado, Kansas, Nebraska, South Dakota, and Wyoming.

THE HEALTH-BUREAU.

Sec. 2. That there shall be established in the Treasury Department, under the direction and supervision of the Secretary thereof, a Bureau of Public Health, to consist of a commission of fifteen, of whom eleven shall be appointed by the President, by and with the advice and consent of the Senate, as follows, viz.: One medical commissioner from each of the "Sanitary Districts of the United States," provided in Section 1 of this Act, and two commissioners at large; the compensation of the appointed commissioners, when actually engaged in

the performance of their duties under this Act, shall be $10 per diem and reasonable expenses.

The other four members of the commission shall be the Surgeon-General of the Army, the Surgeon-General of the Navy, the Supervising Surgeon-General of the Marine-Hospital Service, and an officer learned in the law, detailed by the Attorney-General from the Department of Justice. These four members shall receive no compensation.

ANNUAL SESSIONS AT WASHINGTON.

Sec. 3. That the members of the commission shall meet at such time and place as may be designated by the Secretary of the Treasury, and organize by the election from their own number of a president who shall be one of the members at large and who shall receive $5 per diem in addition to the $10 per diem provided in the last section, when actually engaged in the performance of his duties under this Act.

The commission may appoint a secretary, not one of its number, and fix his salary at a sum not exceeding $3000 annually. The commission shall thereafter meet annually at Washington, on the first Tuesday of October, and at such other times and places as the president of the commission, with the approval of the Secretary of the Treasury, shall designate.

A COMMITTEE OF HEALTH SENTINELS.

Sec. 4. That there shall be an Executive Committee of the commission, consisting of its president, the Surgeon-General of the Army, the Surgeon-General of the Navy, and the Supervising Surgeon-General of the Marine-Hospital Service and the officer detailed by the Attorney-General.

The commission shall from time to time prescribe the duties of the Executive Committee, and may make all needful rules and regulations for its own control and for the guidance and discipline of all its officers and employés, and shall establish all rules and regulations for the government of national sanitation in all of its foreign and inter-State relations and special departments in the enforcement of the provisions of this Act.

EXTRAORDINARY CONFERENCES WITH STATES.

Sec. 5. That when, in the opinion of the president of the commission, the interests of the public health would be promoted by a conference of the commission with the State Boards of Health of the several States, or of any sanitary district or districts, he is hereby authorized to invite, with the approval of the Secretary of the Treasury, said State Boards of Health, or such number thereof as he may designate, each to delegate one of its members to meet the commission in conference at such time and place as he may appoint. The president of the commission shall be the president, and the secretary of the commission shall be the secretary of any such conference. The delegate in attendance upon the conference from each State Board of Health shall be entitled to receive reasonable compensation for expenses for a session not exceeding three days, to be paid on vouchers provided by the Secretary of the Treasury.

Medical Practice in Colorado.—The Colorado State Board of Medical Examiners announces that hereafter it will recognize only diplomas from three-year schools as entitling their holders to license. The courses of lectures must have been of at least twenty weeks each, and have been given in three separate years, and a preliminary examination must have been required. Instruction must have been given in anatomy, chemistry, physiology, pathology, materia medica and therapeutics, obstetrics and gynecology, surgery, medical jurisprudence, theory and practice of medicine, and hygiene.

In default of such a diploma the candidate for license must pass an examination in anatomy, chemistry, physiology, pathology, surgery, obstetrics and gynecology, and theory and practice of medicine.

A Meeting and Banquet of Medical Editors attending the Pan-American Medical Congress will be held in Washington, September 4th—the day preceding the assembling of the Congress. Particulars may be obtained from Dr. I. N. Love, 3642 Lindell avenue, St. Louis, who has been appointed Chairman of the Committee of Arrangements.

A Professorship of Ophthalmology at Harvard, it is announced, is to be endowed in the sum of $25,000 by Dr. Henry W. Williams.

BOOKS AND PAMPHLETS RECEIVED.

VOL. LXIII. SATURDAY, AUGUST 12, 1893. NO. 7.

ORIGINAL ARTICLES.

INVESTIGATION OF THE OUTBREAK OF BERI-BERI ON BOARD THE BARK "PAX," FROM CEYLON, WITH A CARGO OF GRAPHITE.

BY ALBERT S. ASHMEAD, M.D.,
OF NEW YORK.

THE iron bark "Pax" left Colombo, Ceylon, February 2, 1893, Cochin, Malabar Coast, February 23, with this cargo: Plumbago, in barrels, 1200 tons; cocoanut oil, in tierces, 400 tons; cocoanut fiber, 1200 bales (80 lbs. to the bale); lemon-grass oil, 95 wine cases; nux vomica, 200 bags (100 lbs. to the bag); turmeric, 200 bags (100 lbs. to the bag); ginger, 444 sacks (100 lbs. to the sack); stick sandal-wood, 200 bundles.

The ship had previously carried a cargo of saltpeter from Iquique, Chile, to Dunkirk, Scotland. Thence it went to Cardiff, South Wales, took a cargo of coal, and went to Bahia, Brazil; discharged the cargo there, and after taking a ballast of sea-sand sailed for Ceylon.

I have obtained from Captain Geeseicke the following information regarding his trip: He had exceptionally dry and fair weather during the whole voyage. Only once, in south latitude 24° 12′, east longitude 65° 21′, did he have a little hurricane, which lasted twenty-four hours. The weather was hot throughout. On May 1st the first mate was taken down with weakness in the knees, pains in the calves, swelling in the ankles, and partial suppression of urine. On May 13th he again reported for duty. On May 15th the captain himself and another of the men suffered from the same symptoms. On May 30th they went to work again. On June 7th the same symptoms appeared in three new men; on June 9th in four more. On June 10th one of these reports for duty. During the entire trip all but six of a crew of nineteen were, more or less, affected with the same symptoms. One died—a cabin-boy, twenty-one years old. The captain does not think that the disease of which this man died was beri-beri, but dropsy, of which his mother, sister, and brother had also died in England. The boy had gone to Brazil when fourteen years old, and, according to the custom, was returning, after a residence of six years, to recruit his health. It became evident, however, from the captain's description of the symptoms, that the disease was beri-beri, the same as that with which the others were affected in a minor degree. I understood that he had increasing dropsy up to the neck, loss of power in his limbs, cyanosed face, and dyspnea, dying in the true attitude of pernicious beri-beri—in a sitting position.

The crew was exclusively composed of Europeans. The bark arrived at the quarantine in New York Harbor on Saturday, July 8th. The captain and ten men were sick at that time with beri-beri. On my visit to the ship I found the former convalescent, but with both legs swollen, loss of reflexes, typical "sheep's run" gait of beri-beri, prolonged muffled first sound of heart, and some paralysis of ocular accommodation still persisting. The first mate and six men had been transferred to the Long Island College Hospital. Three other beri-beri convalescents were still on board. The first-mate was said to be very seriously ill. He had vomiting and circumscribed edema on the back. These are both serious symptoms.

That the disease with which this crew was stricken is beri-beri there can be no doubt. Now the question is: To what causes can the outbreak be traced? The information that I have obtained satisfied me entirely that in this case, as in another case of the same kind,[1] that of the bark "H. B. Cann," the cause was carbonic poison.

Here are the details that were communicated to me by the captain and the second mate:

There were in the ship 1200 tons of *pure carbon* which is usually shipped in lumps, packed in barrels, as it comes from the mines. Many of the barrels were in bad condition, while the lumps had fallen to pieces under the influence of an unusually dry heat, and had eliminated their carbonic gases. This became evident by even a superficial inspection of the iron in the hold of the ship. All the iron parts were incrusted as if by an acid. This appearance could not have been due to the simple contact of the graphite; such a strong corrosive action could only be a chemical one.

Bad smells were coming through the ventilators during the whole trip. These were accounted for by some kind of rottenness in the turmeric. As the cocoanut oil was in tierces and the tierces were afterward found to be only wet with the usual leak-

[1] University Medical Magazine, December, 1892.

age of the oil (which is only 1 per cent. for Cochin and from 2 to 3 per cent. for Colombo oil), and as, moreover, this oil has never been known to undergo fermentation during a voyage, it could not be held responsible for the odor. This odor was so suffocating that if the ship had not been an iron one, the crew could not have tolerated it, because in a wooden ship it would have penetrated through cracks and chinks and made itself felt everywhere; as it was, it was carried alone by the ventilators.

The diet also had nothing to do with the outbreak—there was no want and no fault with it. It included fresh potatoes and lime-juice once a week, and sauer-kraut once a week; a double allowance of lime-juice with grog and quinin was served to the whole crew after the first case had appeared; three-fourths of a pound of preserved meat or one pound of salt meat were served each man daily. During the whole voyage five tierces of salt meat (300 pounds each), and four barrels of pork (200 pounds each) were consumed; from 30 to 36 pounds of preserved meat were consumed every week.

In this case, as in most others, we find the south wind associated with the beri-beri outbreak. There were southeast trades from the Cape of Good Hope to the North Atlantic. The connection between this wind and the outbreak of beri-beri is, in my opinion, a very real, although an indirect, one. The wind is a breeder of intense heat, especially in an iron ship loaded with such heat-absorbing stuff as carbon. This was, said the captain, although he had kept no record of temperature in his log-book, the hottest trip he had ever made. Usually humidity and heat (86° F.) work together in the production of carbonic gases; that is, in cargoes consisting of sugar, wheat, etc., when the trouble arises from fermentation. But in our case, heat alone was enough. because no fermentation was necessary to call into existence carbonic compounds; the direct action of the heat was sufficient.

I have taken pains in this investigation to find out from what source the carbonic poison (which I believe is always the ultimate origin of beri-beri) was derived. I not only found carbon in good disposition for being decomposed, but 1200 tons of it placed during a long sea-voyage in the best condition for decomposition.

NOTE.—There are many among the laity who consider the action of carbon monoxid as an asphyxiating, suffocating one only. But this is a mistake. Carbon monoxid enters the blood without change, and poisons the corpuscles. Dr. Gréhant (*Tribune Médicale*, September 8, 1892, and February 16, 1893) has recorded the results of some very interesting experiments. He has established the law of absorption of the carbon monoxid by the blood of a living mammal, by compounding a series of mixtures of carbon monoxid and air at 1:1000, 1:2000, 1:4000, 1:10,000. He then takes from the carotid of a dog a sample of arterial blood, and extracts the gases at 40°; then he causes the mixture to be inhaled for half an hour, and examines a sample of the blood at that moment. The results of the analysis show that this blood contains less oxygen than the first test-blood, and the figures that represent the carbon monoxid disengaged are exactly proportionate to the quantities of toxic gas introduced into the air. M. Gréhant concludes from these facts that the carbon monoxid is dissolved in the blood-corpuscles, according to the law of Dalton. He has applied his process, using the animal, in order to research and to dose the carbon monoxid in a confined atmosphere.

I shall now give the description of the beri-beri blood, by Dr. Wernich, who did not see in the disease a carbonic poisoning, but, with Dr. Takaki, explained it as an endemic anemia. It will be seen that his description is exactly that of a blood poisoned with carbonic oxids.

"The blood of the beri-beri patients (the examinations of which were, of course, mostly made on the living) showed, compared with the blood of healthy persons, a less vividly red, somewhat dirty coloring, but no especially watery composition. Peculiar adhesiveness or peculiar odor was not found in the samples. Microscopically the number of the red blood-corpuscles did not seem changed. The number of the white seemed not increased. The latter, moreover, showed nothing peculiar in their shape, wherever they appeared distinctly; yet, there were found scattered among them finely granulated, feebly light-yellow, shining, clumpy masses, whose circumference was usually about twice that of the white corpuscles, and sometimes, but rarely, less. It was distinctly visible that the larger of these clumps were not, as might have been thought, compounded of two white blood-corpuscles conglutinated. The red corpuscles, in the initial stages and in the light cases of the disease, did not show themselves different, either as a relative quantity or in shape, from those of normal blood (always observed simultaneously, and under identical conditions). On the other hand, in all advanced cases the size of the single corpuscles was visibly diminished, in comparison with the normal ones. The corpuscles, besides, presented frequently, in these cases, a distinct strawberry or narcissus form (being garnished with small humps and points), and lacked, without exception, the capacity to form rouleaux; while the normal blood, examined at the same temperature, with the same serum or sugar solution, neither lacked this latter capacity nor showed those humpy corpuscles. On account of the often-demonstrated repetition of these conditions, I consider *the small size of, and the loss of cohesion, in the red corpuscles, as characteristic of the beri-beri blood, and the appearance of strawberry-like bodies, still easily recognized as red blood-corpuscles*

(*shrivelling*), *as a marked symptom of advanced cases. All* corpuscles in the blood, down to the smallness of detritus grains, were distinctly colored like the blood-corpuscles. No *colorless* corpuscles, transition-forms between red and white blood cells, could be found in the cases that came to notice, nor any cells of foreign animal and vegetable organisms.

"The spleen was not found enlarged in the autopsies. As far as notes on the matter exist, it was hard but somewhat brittle, of distinct design in regard to the trabeculæ, less distinct in regard to the follicles, and rich in blood. Amyloid degeneration was nowhere discovered."

ADDENDUM.

In conclusion, I wish to refer to an article of mine entitled, "Three Ships with Beri beri Outbreaks, shown to have had Extensive Formation of Carbonic Oxids during the Voyage: Analysis of Beri-beri Blood: Conclusion that Beri-beri is Nothing but Carbonic Poisoning of the Blood," in *Science*, July 28. In that article the following facts appear: There is no deficiency of red corpuscles, no anemia in beri-beri; but in all cases, without exception, a deficiency of hemoglobin; an increase of biliary matter, bilirubin, etc.; the corpuscles are bladder-shaped, and have lost their disposition to form in rouleaux; the deficiency of hemoglobin is due to the presence of oxids of carbon.

The same article contains an account of a coffee-laden ship from Java, whose cargo was carbonized during the voyage, and whose captain and three men died of beri-beri at sea.

I have also contributed an article entitled "Altitude in Spite of Humidity as a Cure of Beri-beri" to the American Climatological Association. In it I try to show that the altitudinal cure, the only really successful one used in Japan during the beri-beri season, is due to the influence of ozone on the blood of beri-beri patients. This influence M. Gerard thus defines: "Ozone transforms albumin into fibrin and hemoglobin into oxyhemoglobin. Its action, when prolonged on this fibrin in the nascent state, re-dissolves it and makes it incoagulable by acids and also by metallic salts. Ozone is the agent of the transformation of blood into fibrin, and the effects of ozonization are produced by the iron contained in the corpuscles, which iron, under the influence of a first ozonization, acquires the property of ozonizing ordinary oxygen."

The prolonged absence of the ozone influence, therefore, and the prolonged presence of its antagonistic carbonic oxids, we may safely conclude are the causes of the extreme fluidity of blood of persons dead of beri-beri. Beri-beri patients who have absorbed poison enough to destroy life show at autopsy an extremely free flow of blood, that is, a complete absence of plasticiity. Convalescents, on the contrary, show increased plasticity.

Messrs. Bertin-Sans and Moitessier show, in a very interesting article in the *Tribune Médicale*, September 10, 1891, that it is the presence of hydrogen and carbonic acid in oxycarbonized blood that prevents the total destruction of hemoglobin. By adding potassium ferrocyanid to oxidized blood, mixed with water, they obtained a solution of methemoglobin, which, heated with ammonium sulfid, gave the spectrum of oxycarbonized hemoglobin. They were able to free their solution from its oxid of carbon by sweeping it for twenty minutes with a current of hydrogen or carbonic acid, or else leaving it during five hours in a vacuum: the addition of ammonium sulfid called forth then only the spectrum of reduced hemoglobin. It will be seen by this that oxycarbonized hemoglobin—a stable combination—can be readily transformed into a mixture of methemoglobin and oxid of carbon. Upon this fact they found their method for ascertaining the presence of oxid of carbon in the blood.

IS IT DESIRABLE AND PRACTICABLE IN MEDICAL SCHOOLS TO TEACH METHODS OF INVESTIGATION IN MEDICAL LITERATURE?

By BAYARD HOLMES, M.D.,
SECRETARY OF THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO.

Readers of American medical journals and medical books complain of the low literary standard of the majority of writers. Two-thirds of the bulk of our professional periodicals are devoted to avowed advertisements, while the reading pages are given up to articles frequently without literary excellence and of questionable motive. It may not be out of place to describe a recent effort undertaken to prepare a class of medical students to write intelligently on any medical subject.

This class consisted of thirty-six men, seven of whom had received the Bachelor's degree from reputable literary institutions, and one of the thirty-six had the Doctor's degree from one of the best Eastern universities. Of the others, eight read one language beside English, and four read two foreign languages. The German, French, Italian, Spanish, Scandinavian, and Russian languages were read by different members of the class. More than half the class were able to read without difficulty in at least one foreign language. There was no case of remarkable illiteracy in the class, and few of its members made any of the more flagrant infractions of the laws of grammar and rhetoric. All were eager, honest students, seeking for medical instruction and not for a diploma alone, as their presence in the class during the optional summer course sufficiently testified.

My own acquaintance with the class was intimate. My knowledge began with their preliminary examination, and was continued in a constant oversight during two previous years. It was furthered by one course of lectures to them, two examinations in bacteriology and six written exercises on the current surgical course. A large part of the class had studied composition for the sake of composition, while a few only held the labor of composition in contempt, and no amount of assistance or friendly

criticism could arouse these few to an application of the importance of a study of purity and clearness.

The object of the course was to assist those men that were already able to write English clearly and forcibly, to write on familiar medical subjects with a mastery of the existing literature.

A lecture was first given, designed to show the material of medical literature. In order to make the impressions more vivid and lasting, copies of the various serials were passed around the class for inspection. In this way especial attention was called to those great fountains of medical thought, such as the *American Journal of the Medical Sciences*, the *Lancet*, *Virchow's Archiv*, and the principal weekly journals of the United States. The more classical text-books were also described, and copies not familiar to the class were exhibited, and the method of consulting them was pointed out. One or two examples of systematic or encyclopedic medical storehouses, such as *Ziemssen's Cyclopedia* and the *Deutsche Chirurgie* of Billroth and Lücke were also exhibited and examined with reference to their future use.

With this limited survey of the material of medical literature my next effort was to show where and how this material could be consulted. The fact was pointed out that there were but five general medical libraries in the United States, and that all exhaustive work in medical literature must, for the present, be done in these five places. Attention was called to the library of the Surgeon General's office at Washington, because of its completeness, and to the Newberry Library, because of its nearness. Through the courtesy of the medical librarian of this library, Dr. G. E. Wire, these exercises were held in the lecture-room of the library, and all the material of the library was placed at our disposal, and every assistance offered for study. The method of indexing the library was briefly described, and each student was required to make the cards for at least one book, with cross-references. The use of the card-catalogue was then explained, and each man was required to pick out references on one subject.

This done, a full account of the method of literary research was given, with much stress laid upon *exact and permanent* notes. A lot of properly shaped tablets and covers were distributed, and every man was exercised in note-taking. All criticisms were made openly before the class, and after the criticism a rewriting was required when indicated. Thus, many of the technical difficulties were overcome before more serious difficulties were met.

When these preliminary studies were completed, those aids to literary research most complete and manageable were described and studied. First the *Index Medicus* was examined, and the plan upon which it is arranged and indexed was carefully studied. Each student had a bound volume of this serial before him. When a general idea of this work had been obtained and one subject looked up as an example, a series of subjects for theses previously arranged was distributed, and one subject, known to be not too liberally represented in the literature, was assigned to each student for a serious effort, and work was begun in earnest. The subjects were all in the line of the work required in the courses being pursued by the men to whom they were given.

When each man had consulted each volume of the *Index Medicus* and had made a list of all the references to the literature that he could find, a week was given for study. Students were advised to follow some such order as the following in preparing the theses:

1. Read the subject in text-books.
   (a) Anatomic. (b) Pathologic.
   (c) Clinical. (d) Historic.
2. Read the subject in encyclopedias.
3. Read the references in the serial literature.
4. Cast the thesis from the notes taken in the reading.

Again the class had the help of the librarian, Dr. Wire, in solving the difficult problems which come to the beginner in the course of such a study. Many of the articles referred to were not acceesible; many were not valuable when found, and some were difficult to utilize. A sufficient interest was, however, aroused to secure results far above that of any previous class-work that it has been my fortune to observe. Some men did their work thoroughly and exactly; others imitated exact work, but produced soulless stuff; while a few failed entirely after collecting with great labor an unmanageable mass of material.

At our next meeting three essays that had been completed were read one after the other before the class, and criticised openly by all. Other finished essays were retained by their writers because by this criticism they saw how to better them. A few who had done the work in the library, and were unable to cast their notes into a thesis, from lack of motive or skill in such work, were assisted by me and by members of the class who volunteered to help.

In addition to the *Index Medicus* and its supplement, the *Catalog of the Library of the Surgeon-General's Office*, similar instruction was given in the use of *Virchow and Hirsch's Jahresbericht*, *Schmidt's Jahresbücher* and the *Archives Générales de Médecine*, and when the subject suggested it, to similar publications in limited fields, such as *Baumgarten's Jahresbuch*, *Centralbatt für Bakteriologie* and allied publications. For the sake of simplicity, however, much was left to availability and individual needs.

Two weeks later all the theses were handed in to me,

together with all the notes and references. This was done so that not only the end-result of the study could be considered, but the method of work could be criticised.

If there were a medical journal for medical teachers alone it would be worth while to publish one or two of these essays, but space and the time of the general reader are too valuable to permit it here.

Many members of the class spontaneously expressed themselves as greatly pleased at discovering this new field of which they had before only indistinct conceptions. A few have continued their studies and are trying to get an exact and comprehensive idea of medical literature, hoping to be abe to do better work next year and after graduation. One man said that he never before appreciated the poverty of the medical curriculum or the absurd brevity of the ordinary course. He said that he saw, as he never had before, the need of the most liberal preparation for the study of medicine and the helpless condition of the unprepared to get the value and enjoyment from medical study which it affords.

This first experiment in teaching methods of thesis-making in medicine, though incomplete in many respects, satisfied me that the teaching of correct methods in literary investigation to our average medical student is perfectly practicable. It satisfied me that while the conservative bias for which medical students have frequently been reproached may lead many to begin this new subject reluctantly, the evident advantages that are to be quickly obtained arouse an interest and enthusiasm in almost every one sufficient to overcome the discouragements of a polyglot literature and an incomplete library. I can unhesitatingly and positively recommend that such a course be made an integral part of the curriculum of every medical school that aspires to be known for its means of education and culture.

CLINICAL MEMORANDA.

HOW POSITIVE MENTAL IMPRESSIONS PROMPTLY CURED A CASE OF HYSTERICAL BLINDNESS.

By JULIAN J. CHISOLM, M.D., LL.D.,
PROFESSOR OF EYE AND EAR DISEASES IN THE UNIVERSITY OF MARYLAND; SURGEON-IN-CHIEF TO THE PRESBYTERIAN EYE, EAR, AND THROAT CHARITY HOSPITAL, OF BALTIMORE.

In the entire range of hysterical enigmas there is no more curious condition than that of complete suppression of an important sense—as, for instance, that of vision. In an eye to every physical appearance normal, blindness more or less suddenly is complained of; continues absolute for weeks, or months, or even years; and then miraculously disappears, leaving the organ in perfect working order.

How this long suppression is effected is one of the unsolved problems in physiology. We have evidences of the existence of this mental faculty when we use the microscope with both eyes open. The eye applied to the instrument can be made to receive impressions, while the other, equally capable, stares at the table in vacancy, unconscious of the presence of the many objects which this eye can take in upon its field of vision. We have also examples of this visual suppression in cases of squint. Here, to be sure, one of the eyes is usually more feeble in visual power. There are, however, many persons with alternate strabismus, in whom both eyes are of equal strength, and yet vision is completely suppressed in the diverted eye.

The accepted explanation is that the image in the eye improperly directed is received upon the marginal, insensitive part of the retina, and makes too feeble an impression for brain-interpretation. This reason is not always satisfactory. When the eye of an adult turns in or out, the sequence of paralysis of one of the eye-muscles, the same marginal portion of the retina transmits so vivid an impression as to produce an extremely annoying diplopia. In hysterical subjects the eyes remain in the correct position, and hence images are made on each central fovea, which is that portion of the retina designed by nature for the most perfect sight; and yet, while each eye is positively free from disease, one eye sees perfectly well and the other, according to the patient's statement, sees absolutely nothing. The cause to which this disturbance is usually assigned is a reflex irritation from some unrecognized distant lesion; but this is not satisfactory. In the case which I here report, there was no attempt to seek or to treat any local hidden cause, for none was suspected. The young lady was not of plethoric habit, but was in fairly good condition, although somewhat anemic. Her medical history was as follows:

Miss J. C. P., the daughter of a practising physician, had been taken from school on account of blindness in one eye, which had come on suddenly four months before. She was a well-grown girl, seventeen years of age, and had been brought up in affluence. Under parental professional care she had taken tonics for anemia, but the eye continued blind. At times she would complain of hemorrhages from this eye, and would show stained handkerchiefs in evidence of her statements. As the eye was at no time injected, and showed no external evidences of disease, the anxious father consulted an eye-specialist in his own State to aid him in the diagnosis. This ophthalmic surgeon suspected the true condition of affairs, called the disease hysteria, and advised a course of tonics. Vision, however, did not come back under this medication. After four long months of constant complaining the father and daughter came to Baltimore, seeking further medical advice. The patient gave a straightforward statement that with the right eye she saw perfectly well, but with the left eye she could not detect even light. She also reiterated her hemorrhagic experiences. Upon most careful examination, one eye seemed the counterpart of the other. There was no trace of any previous pathologic condition which could explain the reported hemorrhages or the

loss of sight. Either and both pupils acted uniformly under light-stimulation. Ophthalmoscopic inspection revealed no disease. The conclusion reached from the examination and the behavior of the eyes was that notwithstanding the innocent simplicity and evident truthfulness of the young lady, the blindness was a simulation, a true hysterical amaurosis. This diagnosis was made absolute when, after trying the weakest concave lens before the good eye, I substituted for it the strongest concave lens of the trial case. Although such a lens must destroy all useful vision when placed before a good eye, she could with equal facility read the No. 20 test-types at twenty feet. This was proof positive that she must have seen it with the blind eye only, yet when I substituted my hand for the strong lens she was, according to her statement, absolutely in the dark. Without hesitation I gave the diagnosis to the father that the blindness was altogether imaginary, and that I would cure her.

He had made arrangements to remain one week in Baltimore, and he requested me to proceed slowly to bring about the desired change without letting his daughter know our suspicions. I prescribed a simple tonic pill to which I assigned the power of curing her without fail. She was to take one three times a day, and they would require just three days to effect the cure; moreover, they would do it suddenly when the seventy-two hours had expired—no sooner, no later. I desired to see her each day at the same hour, avowedly to watch progress, but chiefly for the purpose of fixing the impression on her mind that at the time appointed the lost sight would surely come back. At the end of the third day, in going through the usual trial with the test-types she despondently complained still of no sight whatever in the blind eye, although she had faithfully carried out the treatment. To her the outlook was as black and as blank as on the day of her arrival in Baltimore. I took out my watch, which I continued to keep in hand, and in a positive reassuring tone said: "There lack yet five minutes, and in that time you will surely have evidences of returning vision." She would frequently close the good eye, watching for the promised awakening. Suddenly she exclaimed that the light was coming, and in a minute afterward that she could, with this blind eye, distinguish objects in the room. Before she left my office on that day she read with this eye the finest print, and gave every evidence to her delighted father that she had perfectly regained sight in it. She seemed quite as much pleased with the restoration as was her parent. The miraculous cure was not only complete, but also was permanent. It was another illustration of the many "faith cures" made by physicians and others, and of the influence which a strong mind can have over a weaker one.

CURE OF MASTURBATION IN A WOMAN BY NEURECTOMY.

BY J. S. EASTMAN, A.M., M.D.,
OF BERKELEY, CAL.

EITHER from soreness of heart, disgust, or absolute despair, do we not too often neglect the unfortunate class of masturbators? We know full well that it is a habit that largely prevails, leaving in its wake a destruction of nerve-force and blasting lives. Having under my supervision one redeemed from the curse, built up from a tottering hopeless helplessness to a useful member of society, I am convinced that others can be similarly benefited.

A second reason for reporting this case is that I have been unable to find that any one has suggested an easier or more efficient relief than I offer. I further think my suggestion is in the line of conservative surgery, and may help to preserve the sex and spare the ovaries. Some of the most prominent gynecologists of New York assured me that clitoridectomy would be a perfect relief. Experts of San Francisco assured me that ovariotomy would bring the desired result. Many others of wide repute and experience did not even attempt a reply to my inquiry as to what might be best for such a desperate case.

My case was Miss A., twenty-six years of age, who came to me in September, 1890. Her hands were cold, covered with sweat, and she complained of sleeplessness at night. She was pale, haggard, and emaciated; she avoided society, had lost all interest in books, could not read with interest for five minutes. She was desperately dejected, and demanded relief. She had begun the habit at six years of age—one of the first things learned at public school. The indulgence was one or more times a week, and even as often as six times in one day. At the age of twenty years she had an opportunity to indulge in coition, and repeated it three or four times a week, but always without satisfaction, and generally with more or less pain. While she had the opportunity to have coition she still had sufficient control to enable her to resist self-abuse. When she could no longer practice coition without prostitution, she sought medical advice. Bromids and acid blistering were prescribed, and gave less contentment than an ordinary placebo. The next treatment was the placing of four silver-wire sutures through the labia majora, leaving the meatus urinarius free, and with the long curved ends of the silver wire pointing into the flesh, so that any manipulation would be painful, but still the habit prevailed. The electro-cautery was then applied to the parts, but unfortunately the resulting irritation aggravated the trouble, and she said the act was repeated fifteen times in one day. A council of numerous experts was then called. As her mother was an epileptic, and as the patient showed such symptoms as loss of memory, fainting-spells, and mild convulsions, it was decided to perform ovariectomy, from which she made a rapid and satisfactory recovery, without a single untoward symptom. A year rolled by, and all things seemed well, when the habit again returned as violently as before, and was indulged in both when awake and asleep. Then clitoridectomy was performed, and gave about three months' rest. But the symptoms grew worse than ever. She was now reduced in weight to ninety-eight pounds. She again returned to my office, and said she would gladly submit to any operation that promised relief. Almost in despair, fearing, as had been suggested, that her trouble was of central origin, I made another examination, and found her more sensitive on the left side of the vulva than the right. The fact suggested to me the desirability of a local paralysis. Accordingly, the following morning, in my office, the patient was placed under ether. I cut down upon the pudic nerve on the left side, and found the nerve very

considerably hypertrophied, and therefore very easily located. I dissected and removed about three inches of the nerve, sewed up the wound, and sent the patient home in her carriage. The wound healed promptly; the patient expressed herself as relieved from anxiety, and better in her general feeling than ever before. She has gained in weight from one to three pounds each month, until she now weighs 132 pounds instead of 98. She has become a great reader, enjoys company, sleeps well, and in every way seems restored to a normal condition. Many acquaintances have remarked how she has changed in manner, character, and looks, and she says: "the best of it all is I feel so much better."

Not only have all these desirable changes been wrought, but she has been absolutely free from her curse since the day the nerve was resected, which is now one year and a half ago. Of course, one case is not conclusive, but certain remarkable features of this case suggest the advisability of cutting out the nerve rather than the clitoris or ovaries, and it is certainly much the more simple operation.

CARCINOMA OF THE ESOPHAGUS.

By E. R. AXTELL, M.D.,
Professor of Histology and Bacteriology, University of Denver; Pathologist to St. Luke's and to St. Anthony's Hospitals, Denver, Col.

Malignant disease of the esophagus is sufficiently rare to deserve more than passing notice. Of 9118 cases of carcinoma collected by Tanchon in 1851, only thirteen involved the esophagus. Mr. Butlin (London, 1882) collected but fifty-nine cases of carcinoma of the esophagus, while all records will hardly swell the number to two hundred cases. Yet carcinoma is far more frequent than any other variety of morbid growth in the esophagus, if not more frequent than any other form of esophageal disease.

In the following case the esophageal growth was primary; did not cause secondary infection, and was limited to the esophagus.

Joseph H., sixty years old, a married German laborer, gave a good family history; both patients lived to an old age and both died suddenly, the cause of death not being known. There was no history of carcinoma or of tuberculosis in the family. The patient's health was good throughout childhood and adult life.

In November, 1891, while eating an apple, the patient experienced a peculiar sense of constriction in the epigastrium, which continued thereafter. He was able to eat the apple and took solid food without inconvenience until February, 1892, when he found that he could no longer swallow solid food, even if masticated very finely. If the food were swallowed it would be ejected in two or three minutes, apparently not passing beyond the level of the larynx.

From that time he lived on liquid food. In September, 1892, he found that he had to take his liquid food in small quantities or else it would be thrown up.

He then began using the stomach-tube once a day and he thought that he was able to take a little more nourishment. On passing the tube he could feel it turn on itself. He was able, however, to wash out a quantity of "dirty water." Each day he had a small mushy stool.

The patient complained of a pronounced sense of weight, as though something were growing in the larynx. He had no cough, but at times a large amount of mucus would find its way into the throat and cause some inconvenience. He volunteered the information that he passed but little water, the quantity for three months not having been greater than six or eight ounces in twenty-four hours. Previous to this the amount passed had been fair. Examination of the urine showed a specific gravity of 1028, without albumin and sugar.

During the last year of life the patient lost forty-five pounds in weight, the greater part during the last three months. On physical examination a few moist râles were heard over both lungs. The heart-sounds were weak, but otherwise normal.

An ivory bougie, one-half inch in diameter, introduced into the esophagus, met with obstruction at a distance of twelve inches. A one-fourth inch bougie was also stopped at the same point.

On December 25, 1892, three weeks after the preceding examination, the patient died of asthenia. For a week before his death he was not able to retain any food at all.

The autopsy, made twenty-four hours later, revealed old adhesions over the lower lobe of the right lung. There was also some edema of both lungs. The right lung presented evidences of bronchitis. The heart and other organs of the body were normal.

One and one-half inches above the cardiac orifice of the stomach was found an annular tumor-mass in the walls of the esophagus, at no point more than two inches in vertical diameter. It was hard and nodular and almost completely closed the gullet. A fine probe could be pushed through the small opening without resistance. The mucous membrane over the growth was in a state of ulceration.

The tumor-mass was completely isolated. No secondary growths were found anywhere, and the bronchial glands were not enlarged.

The brain and the chord were not examined. Sections of the tumor-mass were made, and the growth proved to be a typical scirrhous carcinoma, with small spheroidal cells in the alveoli.

In this case there was no history of lancinating pain and no vomiting of blood.

The termination of the case occured one year and one month from the onset of the first symptom, and it was marked by progressive asthenia. No complications supervened.

Gastrostomy in a younger man might have been a useful operation. It was suggested to this patient and refused.

MEDICAL PROGRESS.

Acute Nephritis in the Newborn.—Frees (*Zeitschr. f. Geburtsh. u. Gynäkologie*, Bd. xxvi, H. 2, p. 426) has reported the case of a premature male child of a healthy primipara, in which three days after birth edema of the lower extremities developed, progressively increasing in intensity and extent. There was also jaundice. On the fifth day a cephalhematoma appeared upon the right parietal bone. There was no complication in connection with the umbilicus. The edema began to decline after

the seventh day, and was almost entirely gone by the tenth day. The jaundice at this time also began to disappear. Examination of the urine on the seventh day and subsequently showed that the quantity excreted was greatly diminished, and that albumin and hyaline, granular and epithelial tube-casts were present, together with red-blood corpuscles, renal epithelium, amorphous urates and detritus. The child manifested general apathy, refusing to take the breast, and losing decidedly in weight; the temperature remained subnormal throughout. On the twenty-sixth day improvement set in abruptly, the quantity of urine eliminated increasing, and the amount of albumin diminishing. The child rapidly gained in weight, and was soon perfectly well. It is thought probable that the condition was dependent upon undue irritation resulting from tardy solution of uric acid infarcts in a premature and feeble child. The urine of the mother was free from albumin before, during, and after labor.

Anuria for Eleven Days, with Recovery.—DURING (*Internationales Centralbl. f. die Physiol. u. Pathol. der Harn- u. Sexual-Organe*, B. iv, Heft 4, p. 181) has reported the case of a man, sixty years old, who had suffered for a number of years from gout and renal colic, the urine at times containing small calculi. On one occasion the man was seized with severe pain in the left loin and in the course of the left ureter. The testicle of the same side was retracted. A few drops of urine were passed from time to time at long intervals. There was also vomiting. From this time no urine was passed, despite the efforts of the patient. The bladder was found to be empty. Warm baths, douches, massage, and diuretics were employed, but without avail. On the third day uremic symptoms appeared: vomiting, eructations, somnolence, depression, restlesness, thirst, anorexia. In a short time copious diarrhea set in. On the eighth day the man's condition became alarming, the uremic symptoms becoming more pronounced. This condition continued until the eleventh day, when, while straining at stool, a large amount of bloody urine was passed by the urethra. The urine was not preserved and a possible calculus could not be looked for. During the first ten or eleven hours between twelve and fifteen quarts of urine were passed. The threatening symptoms at once subsided, and in the course of forty-eight hours the patient felt as well as usual.

Rupture of Tendon of Quadriceps Femoris: Tenorrhaphy.—KÖHL (*Corr.-bl. f. Schw. Aerzte*, 1893, No. 13, p. 454) has reported the case of a man who, in descending a declivity with a heavy weight upon his back, slipped and made a strenuous effort to maintain his equilibrium. In this he succeeded, but upon attempting to walk he found that he could not extend the right leg. The patella was in its proper place and movable laterally; on attempts at extension its relations were not changed. Above the patella a firm mass was appreciable; above this there existed a distinct depression, and a little beyond this there was a second resistant mass. It was recognized that the tendon of the quadriceps had been ruptured, and it was determined to expose the parts and suture the severed extremities. The rupture was found to be an irregular one, and to have taken place less than an inch above the attachment of the tendon to the patella. The proximal extremity contained three small cartilaginous nodules, which were removed. There was also one free nodule in the joint. After the extremities of the tendon had been sutured and drainage provided for, the wound was closed and the leg extended and encased in an immobile dressing. At the end of six weeks massage and flexion were instituted, and in a short time the man was able to resume his occupation, a slight impairment of flexion persisting.

Enteric Fever; Perforation; Recovery.—MCCALL (*British Medical Journal*, No. 1697, p. 62) reports the case of a woman, thirty-four years old, who, upon the sixteenth day of an attack of enteric fever, after eating half a dozen unripe plums surreptitiously obtained from a child, was seized with violent pain and vomiting and other evidences of collapse. The temperature fell to 97°, the extremities became cold, tympanites became marked, and death seemed imminent. Under stimulating treatment, including the application of warmth, the woman rallied and gradually improved. A considerable area of dulness formed in the cecal region and slight dulness in both flanks. On the twenty-second day the dulness over the cecum had become better defined, while that in the flanks was disappearing. Eleven days later fluctuation was detected in the midst of the cecal dulness, and poultices were applied until pointing took place. On the thirty-third day a small amount of matter was passed per rectum. Six days later eighteen ounces of badly smelling purulent fluid were withdrawn from the area of cecal dulness by means of an aspirator. After another interval of six days eight ounces more of pus were withdrawn. Thereafter convalescence set in, and perfect recovery ensued.

Epilepsy and Enteric Fever—LANNOIS (*Revue de Médecine*, No. 6, 1893, p. 492) has reported the case of a woman who had been paralyzed upon the right side from the age of eight months, and had had epileptiform seizures from the age of thirteen, when the paralysis became aggravated, and tremor appeared in the right lower extremity. During a protracted attack of phlegmonous erysipelas of the thigh the convulsive attacks remained in abeyance, while during a subsequent attack of enteric fever they recurred with increased frequency. That the mere elevation of temperature was not the real factor in the control of the paroxysms appears from the fact that it reached the same degree in both instances. It must, therefore, be concluded that the toxin of the streptococcus of erysipelas has a restraining influence upon the occurrence of epileptic attacks, while the toxin of the bacillus of enteric fever, on the contrary, rather favors the occurrence of the paroxysms.

A Coin in the Alimentary Canal for More than Nine Months.—KEARNEY (*Lancet*, No. 3644, p. 27) has reported the case of a child, a year and seven months old, who swallowed a copper coin about as large as a one-cent piece. A diet of boiled bread and porridge was recommended, but the coin was not passed. Four months later it became necessary to treat the child for bronchitis, the passage of the coin meanwhile not having been observed. At the expiration of more than nine months the coin was expelled, the child having been none the worse for the protracted lodgment of the foreign body.

SATURDAY, AUGUST 12, 1893.

CHARAKA-SAMHITA.

IN these *fin de siècle* days it has become fashionable to affect to sneer at the mere suggestion of the possibility of there having been wisdom among the ancients. PUNDIT AVINASH CHANDRA KAVRITANA,[1] a member of a race that delights to trace its origins and find its exemplars in immemorial antiquity, has adopted the most effective means of answering and silencing such sneers, in the publication of an English translation—virile and idiomatic—of the oldest and most celebrated Hindu treatise on medicine. *Charaka-Samhita*, we should judge, bears much the same relation to the medicine of the East as the aphorisms of HIPPOCRATES do to that of the West. To the student of medical history the value of the work is inestimable; and the parts thus far published contain promise that there will likewise be some contributions of decided value to medical practice. As to this, however, we are not as yet prepared to express a more definite opinion. Certainly there are careful empiric observations, especially in the domain of materia medica, that deserve attention and investigation. While the hygienic rules are good and show that the ancient Hindu physicians were acquainted with much that passes for novel, yet they tell us nothing we do not already know. This detracts not from their historic value, but merely from their practical importance at the present day.

As is to be expected, we find among many wise and highly practical maxims others based upon superstitions of the time, local customs, or peculiar religious observances; but even our latest text-books cannot claim to be free from similar blemishes. How long is it since distinguished obstetricians practised and advised a most elaborate ritual, now happily almost obsolete, founded upon a superstitious, or, at least, irrational, awe of the microbe fetish?

Opening the work at random, we find among others illustrating a broad view of the fundamental principles of medicine, observations like these:

"Incurable diseases are . . . . of two kinds, those that are capable of being suppressed and those that have no treatment." "Even diseases that are incurable in consequence of the exhaustion of one's allotted period of life may be kept in a suppressed state by regulated diet and (proper) nursing."

Inseparable from the art of healing, in the ancient author's view, was the art of right living. But right living has not only a physical, but also a psychic aspect; and the psychic life is not only intellectual, but moral. Hence we find metaphysical analyses as well as elevating spiritual reflections and moral precepts intermingled with therapeutic and hygienic dicta. Again we cite at random:

"Emancipation can never be theirs whose minds are still stained by the faults of Passion and Darkness." "One should cherish emulation in respect of the causes of other persons' prosperity, but should never be jealous of that prosperity." "Keep the senses under subjugation." "One should wear every day clean and well-washed clothes; be always cheerful, and use agreeable perfumes." "One should bathe twice in the day, . . . always keep one's outlets (for urine and excrement) and one's feet perfectly clean and well washed." "One should constitute one's self the friend of all creatures, ... pacify the angry, reassure the frightened, redress the woes of the distressed." "The absence of harmony in respect of the ingredient humors (of the body) is disease; for their harmony constitutes our normal condition."

The subject of materia medica is extensively considered. Six hundred purgatives, five orders of astringents, remedies for vomiting and hiccough, agents that alter the color and consistency of feces, increase or diminish the excretion of urine, promote or allay sweating, etc., etc., are enumerated and classified. The editor gives in foot-notes the modern names of the plants specified. Much attention is paid to inhalation of the fumes of certain

[1] Editor of Chikitsa-Sammilani (Medical Journal in Bengali), Practitioner of the Hindu System of Medicine, etc., etc.

medicaments; thus there are described smokes for the nose and the throat, smokes for purging, etc. The directions as to the method of inhalation are precise, and failure is ascribed to departure from the proper routine. The subjects of heredity and re-incarnation are discussed from both theologic and medical standpoints. The work is published by subscription in fascicules,[1] of which five have thus far been issued. The rapidity of issue will depend upon the encouragement received by the editor. It is proposed to issue twelve parts yearly until the work is completed. As it is a substantial contribution not only to the history of medical literature, but also to the history of human progress in many departments of thought and knowledge, we trust that the subscriptions will be sufficiently numerous to insure the speedy completion of the publication. For ourselves we gladly acknowledge our debt to MR. KAVRITANA for the enlightenment and pleasure which we have gained from the pages his industry and enthusiasm have placed before us.

MOTOR AGRAPHIA.

SINCE Broca demonstrated the localization of the center governing the function of speech in the third frontal convolution of the left cerebral hemisphere, the most marked advances have been made in cerebral localization, and we may add, also, in spinal localization as well; but with this, however, we do not at the present moment wish to deal. Not only have centers been isolated that control the functions of different parts of the body, but it has been shown that the defect variously described as alalia, aphemia, or aphasia is a most complex one, constituted of numerous diverse elements, and in its relations not restricted to lesions of the left third frontal convolution. These lesions are responsible for the motor form of aphasia, the patient preserving the faculties of ideation and comprehension, but being unable to revive the motor mechanism of expression. If the power of expression in spoken language be at fault, the defect is termed aphemia; if the power of expression in written language, agraphia; if the power of expression by signs or gestures, amimia. Lesions of the auditory center in the adjacent first temporo-sphenoidal convolution and of the visual center in the angular gyrus occasion sensory aphasia. In addition, there may be impairment of the memory of words—amnesic aphasia. In conjunction with sensory aphasia there is likely to be an inability to recognize spoken words—word-deafness; or to distinguish sounds at all—mind-deafness; or an inability to recognize printed or written words—word-blindness (alexia); or to comprehend the significance of signs or gestures—apraxia; or to recognize objects at all—mind-blindness. These defects may be variously associated, with the result of giving great complexity to the clinical picture. Thus, in a case of word-blindness, the patient is equally unable to read and to write, either spontaneously or from dictation, or to transcribe. In another instance, he may be unable to write spontaneously, but may be able to transcribe. In this way we may have a sensory and a motor agraphia. CHARCOT and DUTIL (*Comptes rendus hebdomadaires des Séances de la Société de Biologie*, No. 24, 1893, p. 130) have recently reported a case that would seem to demonstrate that in addition to agraphia of sensory origin, resulting from a lesion of the visual center or in the path of the fibers connecting this center with the motor center for the upper extremity, there may be a motor form of agraphia which bears the same relation to written language that logoplegia bears to spoken language. The case was that of a woman in which, after an attack of right hemiplegia, with paralysis of the tongue, at the age of forty-four years, the ability to write spontaneously and from dictation was lost, although the ability to transcribe was preserved. There was neither word-blindness nor word-deafness. At the age of fifty-five, left hemiplegia took place, with complete loss of speech. A third and a fourth attack occurred at the age of sixty-one, and death took place at sixty-nine. At the post-mortem examination areas of softening were found in the cortex of the left central hemisphere, (1) at the posterior extremity of the second frontal convolution, and (2) in the middle portion of the second frontal; upon the right side, (3) at the anterior extremity of the third frontal and the posterior portion of the third frontal, extending into the ascending frontal; and (4) at the foot of the ascending frontal and ascending parietal; and (5) in the posterior portion of the ascending parietal. Two additional areas of softening were found at the base of the right hemisphere. The last and the third were thought to have given rise to no symptoms; the second and fourth to have caused the symptoms of pseudo-bulbar palsy that had been present; the fifth the paresis of the

[1] D. C. Dass & Co., 200 Cornwallis Street, Calcutta, India. Price, per part, 1 rupee: in advance, for the whole work, £3, post free.

left side of the body; while the peculiar form of agraphia was ascribed to the lesion at the posterior portion of the left second frontal convolution, where it is assumed the center for the coördination of the movements concerned in writing is situated. In the discussion that followed the presentation of the report, DEJERINE pointed out the difficulty of isolating and localizing a purely motor agraphia in the presence of a lesion of the motor speech-center, and of reconciling the hypothetic existence of a center for writing with the fact that this function may be performed by the feet as well as by the hands. The second objection does not appear to be a real one, for it can be conceived that the motor center for writing may be a higher one connected with the lower centers for the hand and the foot, either of which may govern the peripheral mechanism of the act of writing. The subject is a most intricate as it is a most interesting one, and much careful observation and thorough study will be required for its elucidation.

EDITORIAL COMMENTS.

Signing Medical Testimonials.—Not long ago the enterprising manufacturer of a much-advertised disinfectant sent around among the physicians of Philadelphia an attractive young woman, who asked for signatures to a certificate of the virtues of this particular article. To further her appeal, she exhibited a list of those who had already signed the testimonial. This list was a singular collection of names—illustrious and insignificant, regular and homeopath (another point of resemblance for a former President of the Philadelphia County Medical Society), writers and teachers of various degrees of fame or notoriousness, large-appearing men who need sign nothing, and little men—proud, perhaps, to sign anything—together, alas! with a number of editors of medical journals.

All these men, a curious and inquisitive examiner discovered, certified that "from an experience of many years in hospital, private, and household use," they were convinced that this so-called disinfectant "possesses most completely within itself *all* the *radical and essential elements required for complete disinfection!*" And, naturally, they "heartily indorse and commend its use, not only to the profession, but to the public in general."

But what they certify to is false. Neither this odorless deodorizer and colorless decolorizer nor any other like preparation fulfils the conditions of the testimonial referred to. Many a gallon of it is, by medical sanction, wasted in sprinkling sheets hung across doors behind which contagious diseases are at work, or stands uselessly in saucers in rooms where disease-germs are holding carnival. But everybody who knows what every medical adviser ought to know, knows that no disinfectant whatever can act at a distance, that no "ides" or "ines" of any kind can kill a germ unless its head is held under it; that stories of aërial disinfection belong to a class of fables that it is not prudent to tell to enlightened men and not quite honest to tell to those who confide the care of their health to us.

There are those who, thinking of these things, decline to sign such false and foolish testimonials as the one referred to. But those who sign—why do they do it?

The Relation of Wealth to Health.—Mr. Marcus T. Reynolds is the author of the prize essay of the American Economic Association on "The Housing of the Poor in American cities." It is a work full of instruction, and inspired by the noblest spirit. From it we learn the unexpected fact that the death-rate of the tenement-house population of New York is slightly lower than that of the remaining population of the city, or, in other words, that the death-rate is highest in the houses containing the fewest inhabitants. It seems that the death-rate of persons of five years of age and over decreases with the increase in the number of tenants, while the death-rate of children under five years increases until there are more than eighty tenants to a house, after which it decreases. The explanation of Mr. Reynolds is that the tenants of the larger houses are under closer sanitary inspection, and also that the removal thence of the sick to hospitals is more frequent. He suggests, too, as a possible reason for the lower death-rate of "the poorer classes," that "they pass much of their lives out of doors, and when indoors live in rooms without carpets or papered walls to catch and propagate microörganisms, with bare floors that are washed frequently."

"The Union for Public Good," of Baltimore, is an organization that deserves both success and imitators. Its scope may be considered rather large, but its *raison d'être* consists in the truth of the old saw that what is everybody's business is nobody's business. There are thousands of abuses and injuries to the public health in every city that go on because it is nobody's business to call attention to them or to try to make headway against them. When the Englishman is offended at something of the sort he grumbles, writes to the *Times*, and then—the nuisance goes on as before. The purpose of the Baltimore society is to promote the good government, health, and prosperity of the city, etc. In short, it is a general grievance committee, which proposes to remedy public moral and physical pathogenic tendencies and habits, so far as they affect the public health and well-being. The medical profession is well represented in the association, and certainly has by its aid an excellent opportunity to make effective many measures of sanitation and preventve medicine.

Increase of Insanity and Pulmonary Tuberculosis Among the Negroes of the South.—The responsibilities and struggles of the Southern negro resulting from his sudden manumission are sadly affecting his health. According to Dr. Powell, superintendent of the Georgia State Asylum, there are now over a thousand insane negroes in Georgia, while thirty years ago there were but forty-five. Greater accuracy in reporting cases doubtless explains only a part of the increase, but Dr. Powell attributes about 75 per cent. of the insanity directly or indirectly to the use of alcoholic liquors, which the slave

could not get. Hence is again illustrated the old truth, that there may be too much freedom. As to pulmonary tuberculosis, Dr. Hubbard, of Nashville, Tenn., shows by the health-reports of six Southern cities that the mortality from this disease is four times as great as among the whites.

The Temperance Education Movement has for its object the utilization of the public schools as means of teaching physiologic temperance. The movement deserves all praise, and is evidently slowly securing the success that comes from an intellectual and determined grappling with the sources of evil. It is said that the study is legally made mandatory in every public school in thirty-six of forty-four States, and in every school under Federal control. The want hitherto of the requisite text-books, information, and systematization concerning the study has so far been a serious drawback. But next year a volume for teachers is to be issued, entitled *Normal Studies in Physiological Temperance*, and a series of monthly advices is now issued with the title of "Scientific Temperance," under the superintendency of Mrs. Mary H. Hunt, of Hyde Park, Mass.

A Pan-American Pharmacopeia is proposed by the officers of the Section on Materia Medica and Pharmacology of the Pan-American Medical Congress. This is a healthy movement, and should receive hearty professional support. All great sciences tend to unity, and especially as to their instruments and methods. The pharmacopeia is a body of rules and methods that should be uniform for all physicians. It is a pity that different nations should not have a common pharmacopeia, and this attempt to amalgamate and unify the pharmaceutic and pharmacologic sciences and practices of the American people should enlist the coöperation of those who attend the Congress. The President of the Section is Prof. Joseph P. Remington, and the Secretary is Prof. F. G. Ryan, No. 3739 Brown Street, Philadelphia, to whom communications may be addressed.

Tracts for the Prevention of Tuberculosis for Gratuitous Distribution are now offered by the Pennsylvania Society for the Prevention of Tuberculosis (E. Leslie Gilliams, 727 Walnut Street, Secretary), Philadelphia. These tracts are written in common technical language, so that the laity can understand them, and physicians should make themselves local distributing agents for scattering among the community the knowledge of the simple and highly-important means of preventing the spread of the "king of diseases." Membership in the society costs only one dollar.

Charity-organization.—All who are interested in charity-organization, the proper distribution and use of alms, the sanitary improvement of the poor, the proper relations of the hospitals to the community, etc., should procure a copy of the Fifteenth Annual Report of the Charity Organization Society of Buffalo, N. Y., a pamphlet that shows what noble efforts are being made and what splendid success is being achieved in the special fields chosen. Every city should have such a society, and physicians should be leaders in the movement.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, held at Long Branch, N. J., July 25, 26, and 27, 1893.

FIRST DAY—JULY 25TH.

The President's Address was delivered by DR. HENRY M. LYMAN, of Chicago. He called attention to the predisposing causes of diseases of the nervous system, and said that the simple recognition of disease is not sufficient; etiologic classification is also necessary. He then dwelt upon the subject of rheumatism affecting the nervous system, the marked forms of which, chiefly affecting sensation, are not so commonly recognized and are frequently ascribed to other causes. They are usually observed in elderly persons of nervous temperament and arthritic diathesis, and differ from many other similar disorders of sensation in being transient, migratory, and of brief duration. Among these ailments is a prickling of the surface of the skin, often universal, but sometimes limited to certain points, where the patient experiences a sudden sharp prick, like a flea-bite. Another disorder of cutaneous sensation often affects the scalp, and is occasioned by irritation of the superficial nerves of that region. The duration of the attack rarely exceeds a single day. Closely associated with these disorders are the various transient perversions of sensation that may be felt in the Eustachian tubes, the pharynx, and about the fauces. Another of the symptoms of masked rheumatism is a peculiar and disagreeable feeling in the tongue. This sometimes assumes the severity of a genuine neuralgia, and manifests a greater degree of persistence when associated with obesity, diabetes, or gout than when related to rheumatism alone. The esophagus and fauces and sometimes the muscles of the eyeballs are similarly affected. Often there is a paroxysmal cough, associated with headache. The most distressing of all these forms of pain is gastralgia. The previous history and the concurrence of other rheumatic symptoms of a more stable character will, of course, add greatly to the certainty of the diagnosis.

DR. SMITH BAKER, of Utica, read a paper entitled "Heterogeneous Personality," which he defined as that condition in which the characteristics of ancestry are not blended into a permanent whole. He reported the case of a little girl who presented frequently recurring attacks of functional perversions and distress, which could not be satisfactorily explained except upon the inference that the dissimilar traits noticeable in her grandparents had not been blended in the personality of her mother and so had proved to be the ground-field of the grandchild's affection. The question as to the legitimacy of such a view can never be answered intelligently until the commoner facts of family life shall have been more minutely studied. Thus, such trite matters as dreams, somnambulism, the solving of problems unconsciously, or subconsciously, the up-rush of facts and arguments in the act of composition, and the play of genius, should be investigated.

Inquiries in states of acute illness, and the study of moods and transformations of character, etc., all

should receive more attention by physicians in order that causation in cases of functional derangement may be the more accurately conceived. In doing this, assistance may be found in many instances of so-called reflex disease. Heterogeneous personality should always be looked for in the neuropathic constitution; but more particularly is this of use in considering the problems presented by neurasthenia and the sexual perversions. Not so frequently, perhaps, is the trouble owing to the commonly assumed overwork, etc., as to the unceasing warfare within between the "lower" impulse and the "higher" determination. Students, professional men, and many others whose physical abnormities or mental peculiarities reveal the sensitive, easily impressed nature, are especially prone to be victims of the uncoalesced personality. Its bearing upon questions of marriage and parentage renders it worthy the attention of all.

Dr. Lyons, of New York, referred to the opposite sides of character as seen among the insane. An educated woman may be agreeable and lovable in her normal condition, but vicious when in the abnormal state. The case of a patient was related who would frequently apologize and do her utmost to resist the impulses to do wrong. The opinion was expressed that such behavior might be due to abnormity in the development of the cerebral hemispheres or to some interference with the circulation.

Dr. Parsons, of Sing Sing, expressed the view that the tendency to evil thinking and acting observed in some persons might be overcome by suitable environment. The absence of restraint, after a time, permits of a continuance or permanency of the abnormal condition.

Dr. Hinsdale, of Philadelphia, spoke of two authenticated cases of double-consciousness. He maintained that the medico-legal features of such cases, as well as those of changes in personality, are of special interest and should be reported and carefully analyzed.

Dr. Seguin, of New York, held that atavism is the more rational explanation. Blending of the characteristics of ancestors occurs normally. It is not right to confuse double-consciousness of an epileptic nature with conflicts of character and personality.

Dr. J. J. Putnam, of Boston, said that the treatment rested upon the systematic development of character. Hypnotism has taught much in regard to this condition, and brings out in a striking manner certain phases of character. He recommended the development of the inhibitory powers.

Dr. F. X. Dercum, of Philadelphia, stated that the case reported by Dr. Baker recalled the fact that there is lower vitality at certain epochs in women. Relationships between states of health might account for the peculiar mental variations.

Dr. Baker referred to the various definitions of personality as not being sufficiently inclusive of the facts to be of accurate use. He urged the importance of the study of the subject, especially in its bearing not only upon the causation of actual disease, but in its relation to educational ideas and practices as found to-day in our school-system. In this way may be found means of obviating detrimental traits, and also of making dominant those more desirable and healthful.

Dr. Matthew D. Field, of New York, read a paper entitled "Detention-Hospitals for the Insane." After speaking of the wrongs inflicted upon the insane by committing them to county jails and prisons, there to mingle with tramps while awaiting the appointing of physicians to pronounce upon their mental condition, he gave a description of the Reception Pavilion for the Insane at Bellevue Hospital, and the methods of examination and commitment by the city examiners. He declared the pavilion to be in every respect a hospital, with resident physicians and competent trained attendants. Though a plain and inexpensive building, it served its purpose very well. He advocated the establishment in all large cities of similar hospitals for the reception of those suspected of lunacy. He said that an ideal institution for this purpose would be a hospital constructed on the pavilion-plan for the reception of the insane, inebriate, and neurotic, with a small amphitheater and sufficient wards for proper classification and detention for a reasonable time. A competent visiting, resident, and examining staff of medical officers should be chosen and clinical instruction regularly given. Such a hospital would secure prompt, humane, and scientific treatment. The opportunity for longer observation, securing histories and examinations, would result in more complete and accurate certification. There being no need for hasty transfer to other institutions, the feeble, sick, and certain selected cases could be detained for treatment, and clinical instruction would be easily accessible to the entire medical profession.

Dr. Knapp, of Boston, said that there are no detention-hospitals in Boston, and that no urgent need for them has been felt under existing laws. A few emergency cases requiring immediate restraint are admitted to the general hospitals. Otherwise they can be taken at once to the nearest asylum on emergency certificates. These consist of two separate certificates. A bond must be given by the superintendent, or one of the physicians, to the effect that the patient is to be formally committed, or released within five days. This system has proved eminently satisfactory, and has rarely been abused.

Dr. Mills, of Philadelphia, stated that the method described by Dr. Field is in vogue at the Philadelphia Hospital. There is a detention-ward for isolating cases of insanity. Two physicians are assigned to examine these patients before commitment. This ward has also been used for several years for clinical instruction.

Dr. Preston, of Baltimore, remarked that the lunacy laws of Maryland are inadequate. Endeavors are being made to establish a detention-ward. At present insane patients are kept at police-stations, as no general hospital is prepared to receive them. This method of dealing is entirely unsatisfactory.

The President said that in Chicago there is a detention-ward in the City Hospital in which cases of insanity are kept until transferred. The commitment laws of Illinois are now quite satisfactory.

Dr. Frederick Peterson, of New York, read a paper upon "The Temperature in General Paralysis of the Insane," which was based upon observations, made with the assistance of Dr. Langdon, on twenty-five cases in the wards of the Hudson River State Hospital for the Insane. The temperature was taken every two hours for one week in each case, and in ten cases in the two axillæ simultaneously from every two to four hours for a week.

It was found that the average bodily temperature corresponded with physiologic norms. The diurnal oscillations also corresponded to physiologic norms. Asymmetric axillary differences were so small that they could not be considered as abnormal, and certainly not of any diagnostic significance.

When unusual variations of temperature occur in general paretics, the cause must be sought for in conditions not related to the pathologic phenomena, but depending upon other thermogenic features unrecognized by the physician, or "masked" by the mental state of the patient. Thus, in one case an increasing hyperpyrexia was noted during the seoond week, but the pneumonia causing it was "masked" until the fifth or sixth day, the patient dying on the sixth day. In another case, in which the highest single daily oscillation was 3.4°, and the average daily oscillations for the week 2.2° Fahr., the patient had bedsores on the sacrum and heels, and was undoubtedly septicemic. That the temperature might vary in the paralytic seizures of these cases was not gainsaid, no observations having been taken in such conditions.

DR. GRAY, of New York, said that a large number of different pathologic conditions are often included under the name of general paresis. Some represent the terminal stages of intra-cranial syphilis.

DR. CHARLES K. MILLS, of Philadelphia, said that the diversity of the manifestations of general paresis will account for the different experience of various observers.

DR. JOSEPH COLLINS, of New York, read a paper entitled "The Anatomical Changes in the Spinal Cord in an Old Case of Infantile Paralysis," demonstrating numerous sections and reporting the history of a case.

DR. G. M. HAMMOND, of New York, read a paper on "Progressive Muscular Atrophy." He exhibited microscopic specimens and made a pathologic report of two cases, and referred to the fact that considerable confusion is occasioned by the misapplication of the term "peroneal type" to a disease totally dissimilar to the one under consideration.

The first patient was a woman, forty-six years old, without a history of gout, rheumatism, or syphilis, who, a few days after stumbling over a chair and bruising the right shin slightly, was unable to walk as well as previously. In a little while marked weakness of the flexors of the foot and the extensors of the toes developed. In the course of a year there was complete paralysis of the entire right leg, with reaction of degeneration, loss of power, and of electric contractility in the anterior tibial muscles of the left leg, and atrophy and loss of power in the thenar and hypothenar muscles of the right hand. Gradually but rapidly the other extremities became involved, and ultimately the abdominal and intercostal muscles were affected. Death took place suddenly from either cardiac or respiratory paralysis.

The sections of the cord showed sclerosis of the pyramidal tracts and atrophy of cells in the anterior horns, and degeneration of Gowers' column throughout its entire extent. The conclusion to be drawn from the clinico-pathologic study of this case is that the muscles of the hand were supplied from the mesial group, and the muscles of the forearm from the anterior group of cells in the anterior horn.

In the second case the disease only affected the muscles of the left thumb. The patient was under observation for eleven years. The case ran the usual course, and was in every way typical. At the time of death all of the muscles from the level of the armpits upward, except the facial muscles, were atrophied, as well as those of the upper extremities. The woman became maniacal, and finally died from exhaustion.

The cord and medulla were examined, and the changes were identical with those described in the preceding case.

The conclusion was reached that these cases demonstrate that progressive muscular atrophy is due to a degeneration of the cells in the anterior gray masses and the antero-lateral white columns; also, that it is superfluous to divide progressive muscular atrophy into different types, because the disease does not invariably begin in the same group of muscles.

DR. SACHS said that while there could be no doubt that the Aran-Duchenne type is of spinal origin, it is not certain that the case of Dr. Hammond represented the peroneal form of progressive muscular atrophy as described by Charcot, Tooth, Hoffman, and himself. If the case were such a one, the findings in the spinal cord would have been of great importance. There is yet doubt whether the peroneal form represents a spinal disease or a peripheral affection.

DR. PUTNAM referred to a case of progressive muscular atrophy in an adult in which there was rapid destruction of gray matter throughout the cord. Despite the violence of the process, portions of the anterior and lateral cell-groups were preserved.

DR. F. X. DERCUM, of Philadelphia, read a paper entitled "Optic Neuritis, Blindness, Deafness, and the Knee-jerk in Cerebellar Disease." He said that many of the symptoms of cerebellar disease are both inconstant and variable. They are difficult of explanation and frequently impossible to correlate.

Seven cases were reported in which optic neuritis, blindness, deafness, and modifications of the knee-jerks were present.

It is a matter of common experience that high grades of neuritis may exist without marked impairment of vision. It seems, therefore, that the added symptom of blindness gives a special significance to the optic neuritis found in these cases. It appears that if for any reason optic neuritis is present in cerebellar disease, it is likely to be intense in degree, and sooner or later associated with total blindness.

The proximity of the quadrigeminal bodies has naturally suggested itself as in some way explaining this blindness. The ataxia and titubation at once suggest disease of the vermiform process. Anatomic considerations, as well as the results of the autopsy in one of the cases, show that if a growth be situated in the vermiform process, especially anteriorly, and if the growth continue to enlarge, it will sooner or later press upon the superior cerebellar peduncles and very probably upon the quadrigeminal bodies themselves. If the relation of the fibers of the optic tract to the primary optic centers be recalled, it can readily be understood how a neuritis should result if pressure or irritation occur at this point. The directness of the irritation will explain why the neuritis should be of a high grade, and, sooner or later, associated with total blindness.

The deafness present in some cases of cerebellar tumor may perhaps be explained in a similar manner. The studies of Spitzka, Monakow, and others, have made it extremely probable that the posterior quadrigeminal bodies stand in the same relation to the auditory fibers as do the anterior to the optic fibers. It would simply be necessary, therefore, that the pressure involve these structures in order that deafness should be a symptom.

The condition of the knee-jerk presents a problem of peculiar difficulty. The loss of knee-jerk in disease of the cerebellum may be ascribed to loss of muscle-tonus.

It is extremely probable that lesions of the cerebellum act as do lesions elsewhere, in one of two ways, *i. e.*, either by destroying tissue, and thus destroying function, or by causing irritation. It is, perhaps, in this way that the fact can be accounted for that in some cases of cerebellar disease the knee-jerk is absent and in others present or even exaggerated.

When the disease was advanced there was loss of reflex action to light.

DR. PUTNAM spoke of a case of long-standing optic atrophy, with practically no other symptom. Although the optic neuritis persisted for two years, the autopsy showed a cyst and tumor of the cerebellum.

DR. PRESTON said that he had noted loss of the muscular sense in two patients. In four cases the knee-jerks were irregular, disappearing and occasionally returning.

DR. KNAPP said that in all of his cases confirmed by autopsy there was neuritis or optic atrophy. In one case in which a cerebellar tumor was suspected, neuritis had not developed. Blindness had not been so constant. In another case the light-reflex was lost when the pupils became dilated. Pressure on the corpora quadrigemina is most likely to produce blindness. Dr. Knapp has never noted deafness. He considered untenable the view that disease of the middle lobe of the cerebellum is responsible for the ataxic gait.

DR. LESZYNSKY, of New York, expressed the view that the concomitant basal meningitis has much to do with the production of the optic neuritis, by extension of the inflammatory process along the nerve-sheath. In many cases the neuritis is a late symptom. When the neuritis or optic atrophy is accompanied by loss of light-perception, the pupillary reflex is always absent.

DR. C. L. WALTON, of Boston, read a paper entitled "A New Method for the Reduction of Dislocation of the Cervical Vertebræ." In illustration of the method, let it be supposed that the left articular process of one vertebra has slipped forward over that of the vertebra below, and has fallen into the depression anterior to the articular process. This bends the head to the left, and turns the face to the right. The reduction is accomplished by extending the head diagonally backward to the right, so as to elevate the articular process, after which rotation to the left replaces the displaced vertebra. The transverse processes on the right act as a fulcrum. The ligaments that hold the vertebra firmly in the false position make no opposition to this maneuver, which requires no force.

In bilateral dislocation the same movements should be made, first on one side, then on the other.

SECOND DAY—JULY 26TH.

DR. C. L. DANA, of New York, read a paper entitled "Akromegaly, Gigantism, and Facial Hemihypertrophy." He related the history of a case of akromegaly with autopsy, and that of a case of gigantism or somatomegaly with some symptoms of akromegaly. The giant had a unilateral facial hypertrophy. The first case was in a full-blooded Bolivian Indian who was exhibited as a giant. He was thirty years old, 6 feet 7 inches high, and weighed 300 pounds. The malar and frontal bones were enormously developed. The thorax measured 50 inches in circumference. Death took place suddenly. On autopsy, the brain was found normal, weighing 55 ounces. The pituitary gland was greatly enlarged, measuring 1 inch in diameter. The thyroid gland weighed 4 ounces. The feet and hands had increased in circumferential measurements. The brain presented interesting peculiarities of fissuration.

The second case was in a professional giant, nineteeen years old, 7 feet 5 inches tall, and weighing 350 pounds, whose muscular development was feeble and who presented several symptoms resembling those of akromegaly. A most curious condition was a progressive unilateral facial hypertrophy, due mainly to osseous growth. It suggested akromegaly attacking only half of one extremity. Only eleven cases of this affection are on record.

Dr. Dana said that akromegaly is sometimes associated with gigantism. He held that many so-called giants are instances of pathologic growth rather than excessive physiologic development.

There is much evidence to show that the pituitary gland has some relation to these disorders. Among twelve autopsies, this gland was found enlarged in ten.

DR. DERCUM said that akromegaly is not associated with increase in the length of bones but in their width. He regarded Dr. Dana's case as one of gigantism with akromegaly superadded.

DR. GRAY said that it is a question whether akromegaly and gigantism are not identical. The pathology of akromegaly is not yet clear.

DR. COLLINS held that akromegaly and gigantism are two separate diseases. In gigantism the changes are in the cellular structure of the diaphyses and epiphyses, principally the former. In akromegaly the changes are confined to the epiphyses. Probably the disease of the pituitary gland stands in a causative relation to akromegaly. Giants may suffer from akromegaly, which is a degenerative disease.

DR. PUTNAM said that he has seen temporary improvement in one case from the administration of thyroid extract.

DR. SACHS expressed the opinion that akromegaly and gigantism are related. Gigantism is a form of physiologic excess, while akromegaly is a distinct morbid condition.

DR. WEBER, of New York, had seen two cases. One had symptoms of myxedema. He was inclined to believe gigantism to be excessive physiologic growth.

DR. MILLS related that he has, after death, found a tumor destroying the pituitary gland in a case in which during life there has been no akromegaly.

DR. J. J. PUTNAM, of Boston, read a paper entitled

"Thyroidectomy in the Treatment of Graves' Disease." After calling attention to the fact that this procedure has been carried out some forty times, mainly by German surgeons, with but two deaths and a very large percentage of cures or improvements, he narrated the case of a young woman suffering from a typical form of Graves' disease, of nine months' standing and with a rather large goiter. The right lobe and most of the isthmus were removed. During and after the operation the patient's pulse ran up very high, and for several days she lay in an extremely prostrated, and apparently critical condition. She then rallied, and at the end of six months her condition was decidely better than before the operation, though far from being cured. The remaining portion of the tumor did not shrink and showed a marked tendency to vascular enlargement. The voice was reduced to a whisper immediately after the operation, but subsequently nearly recovered its natural tone.

The reasonableness of the operation lies in the fact that in Graves' disease certain nervous centers are in a state of extreme irritability. Any means that will cut off a considerable number of excitations from reaching the unstable centers is likely to be beneficial by securing for them a partial physiologic rest. There are various means, such as complete rest, the treatment of the nasopharynx, etc., that may do this in a measure, but no one means is so effectual as thyroidectomy. The operation is, however, attended with a slight risk of death, and with a greater risk of considerable temporary prostration and laryngeal paresis.

DR. WEBER said that he has noted recovery in a patient possessing all of the characteristic symptoms, under the persistent use of potassium iodid. The dose was gradually increased to three drams daily.

DR. B. SACHS, of New York, read a paper entitled "Tabes and Syphilis." In support of the close relationship between syphilis and tabes he pointed out the frequent occurrence of general paresis in association with tabes, and of tabes in the course of general paresis; the occurrence of symptoms in the course of tabes that are often due to syphilis; the ocular palsies; the loss of pupillary reflexes and even the lightning-pains; the effect of treatment with mercurials and iodids upon many of the symptoms of tabes.

A clinical differentiation of cases of tabes which are due to an active syphilitic process was attempted. Among such cases were included those that exhibit complete loss of reflex contractility of one or both pupils, and ocular palsies. A case of typical tabes was reported *in extenso*, in which on post-mortem examination a more recent syphilitic process was found superimposed upon an old typical sclerosis. It was pointed out that the spinal sclerosis may result from degeneration brought about by syphilitic disease of the bloodvessels of the cord. Altered states of the blood may be the prime cause of changes in the bloodvessels.

DR. PRESTON maintained that the syphilitic process is an arterio-sclerosis. Rarely is there hyperplasia of neuroglia without changes in the cells or nerve-fibers. The tabetic process probably begins in the bloodvessels. Traumatism seems to be an important etiologic factor. Improvement and relief of pain have followed the use of nitro-glycerin.

DR. MILLS stated that preceding the development of the sclerosis there may be leptomeningitis and disease of the vessels, which if attacked early might be relieved or removed, but the sclerosis once established, recovery becomes impossible. Posterior sclerosis often advances at intervals by jumps, and these may sometimes be coincident with or may follow the revival of active syphilitic processes.

DR. PARSONS referred to two cases of syphilis, followed by insanity and the subsequent development of spinal symptoms.

DR. SEGUIN stated that he still adheres to the idea that syphilis is only a predisposing cause for the groundwork of tabes. Certain cases occur that are undoubtedly free from any history or evidence of syphilis.

DR. KNAPP mentioned a case of primary syphilis superadded to tabes of two or three years' standing.

DR. WM. C. KRAUSS, of Buffalo, exhibited a new pedodynamometer. The apparatus consisted of a wide, heavy belt, with its inner surface padded, so that its adjustment around the waist will not be uncomfortable. A heavy webbing is looped through the belt, passing over the shoulders and helping to retain the belt in position. A common dynamometer is connected with the belt by means of a strong adjustable strap, permitting it to be lengthened or shortened, according to the stature of the patient. Connected with the dynamometer is a stirrup, the base of which is padded for receiving the foot. Pressure exerted upon the stirrup will be registered upon the dial of the dynamometer and the exact strength of the extensors of the leg can thus be ascertained. The apparatus can be applied either in the standing or in the recumbent posture. The leg should be flexed at the knee at an angle of about 90°. To determine the strength of the calf-muscles the strap should be lengthened and the foot flexed upon the leg.

DR. JAMES H. LLOYD and DR. DAVID RIESMAN, of Philadelphia, presented a joint communication entitled "Infectious Endocarditis with General Septicemia, Complicated with Multiple Neuritis," founded upon the report of two cases.

The first occurred in a man with a typhoid type of fever which had continued for three months, and was complicated with multiple neuritis. The diagnosis of typhoid fever was excluded. The neuritis was irregularly distributed. The patient gradually developed an aortic regurgitant murmur, with a water-hammer pulse. Later, a purpuric eruption appeared. A diagnosis was made of infectious endocarditis, with secondary septic neuritis. At the post-mortem examination immense vegetations were found on the aortic valves, with infarcts in the spleen and in one kidney. Sections of the spinal cord and nerves were shown, exhibiting slight posterior sclerosis of the cord and extensive inflammation of the nerves.

The second case, also in a man, simulated typhoid fever, with yellow-colored stools. At the post-mortem examination multiple abscesses in the brain, a large embolus in the left brachial artery, and an infarct in one kidney were found, togther with a giant-growth of vegetations as large as a pullet's egg attached to the inner coat of the aorta, overhanging the orifices of the innominate, carotid, and subclavian arteries.

DR. C. L. WALTON, of Boston, read a paper entitled "Tumor of the Angular Gyrus," in which he detailed

the history of a case presenting temporal and occipital headache, vomiting, paralysis of the left abducens, double optic neuritis, hemianopsia, word-blindness, aphasia, and word-deafness. An operation was attempted, but the tumor proved too large and diffuse for removal, extending into the temporal, occipital, and parietal regions. The patient lived two months, with comparative relief from pressure-symptoms, including the abducens paralysis. Toward the end the right hand and arm became somewhat paretic. Examination showed the growth to be a glioma.

Dr. Seguin suggested that the ocular symptoms were probably not due so much to lesion of the angular gyrus as to involvement of the fibers of the fasciculus opticus which lie immediately under it.

Dr. E. D. Fisher, of New York, read a paper entitled "Congenital Cerebral Hemiplegia, with Autopsy." He detailed the history of a case presenting complete right hemiplegia, with marked atrophy, exaggerated reflexes, epilepsy, and imbecility. The cranial measurements showed morbid deficiency in the binauricular diameter and facial length. At the autopsy the left central hemisphere was found much atrophied. The right cerebellar hemisphere was also atrophied. The microscopic specimens showed a decrease in the number of cortical cells, but those present were not much diminished in size. There was some loss of acuteness of the angles of the cells, but little pigmentary or granular changes. The cord was but slightly affected.

Dr. Charles K. Mills, of Philadelphia, read a paper entitled "Lesion of the Thalamus and Internal Capsule." The patient had an apoplectic attack in 1877, and died in 1892. The symptomatology of the case included hemianesthesia; paresis with contractures not marked; inability to recognize the position of the affected limbs. Hemianopsia and all affections of the special senses were absent, as were also athetoid and choreoid movements. The autopsy disclosed a hemorrhagic cyst, which had destroyed about two-thirds of the substance of the thalamus, including the entire external tubercle and a large portion of the pulvinar. The anterior extremity and the internal and inferior surfaces of the thalamus were intact. The lesion had to a slight extent invaded the posterior arm of the capsule.

Dr. Wharton Sinkler, of Philadelphia, read a paper entitled "Tumor of the Optic Thalamus," and presented a specimen. He reported the case of an unmarried woman, forty-six years old, who, previously in excellent health, first noticed somnolence and loss of mental vigor. Her manner became indifferent and listless. A little later there was some aphasia, and later still paresis of the right side of the face, unsteadiness of gait, and awkwardness in the use of the right hand. When first seen there was marked paralysis and partial anesthesia of the right side of the face, but no impairment of sensation of the arm or leg. There was decided mental hebetude, but no loss of memory. The woman could not walk on account of unsteadiness. The knee-jerks were exaggerated. The temperature was subnormal and the pulse varied from 48 to 60. The pupils reacted to light and in accommodation. There was no nystagmus or hemianopsia, and no change in the fundus oculi.

The symptoms increased in severity, the temperature rose rapidly, and the patient died. There had been no convulsions.

The post-mortem showed the left optic thalamus to be the seat of a growth as large as a hen's egg, which encroached upon the corpus striatum and posterior part of the internal capsule. The tumor has not been examined microscopically, but is probably a fibroma.

The points of interest are the hysterical symptoms that were present at the onset; the fact that the anesthesia was confined to the face; and the question that arose as to the possibility of operation.

Dr. Dana referred to two cases, one with tumor and another with softening in the thalamic region, in both of which somnolence was a prominent symptom. This phenomenon is characteristic when the posterior portion of the optic thalamus and the neighborhood of the corpora quadrigemina are involved.

Dr. Seguin reported a case with a probable tumor in the thalamic region, with somnolence, which was increased by the use of potassium iodid.

Dr. Dana said that he is familiar with a case in which the iodid acted as a hypnotic.

Dr. Gray said that he has noticed the iodid to produce somnolence in a case of cerebro-spinal meningitis.

Dr. Sinkler added that in his case the somnolence diminished after the administration of the iodid.

Dr. George J. Preston, of Baltimore, read a paper entitled "The Localizing Value of Aphasia." He related two cases of hemianopsia, one with autopsy, in which there was no word-blindness, as might have been expected. A case of mixed aphasia was related and the brain exhibited. The case showed absolute motor aphasia, together with word-blindness, and yet the lesion was confined to the third frontal convolution, the occipital cortex showing no disease. A case was reported in which there was a general disturbance of speech, with distinct mental symptoms; the patient at times being maniacal. Upon the strength of the general disturbance of the speech-processes the skull was trephined over Broca's region, and the under surface of the dura found covered with blood.

Dr. Leonard Weber, of New York, presented a paper entitled "Spinal Neurasthenia." He objected to any single plan of treatment as too much routine, and not likely to be of permanent service to the patient, while a proper combination of well-known methods based upon careful individualization is likely to be of greater benefit.

In the grave forms of neurasthenia caused by mental and physical overwork, the prognosis thus far has not been good, even as to relative recovery. If the reports can be trusted, it would seem that hypnotic suggestion constitutes a remedy of extraordinary power in some of these cases.

The history was related of some cases of severe neurasthenia brought about by protracted mercurial inunction, and another caused by prolonged daily use of small doses of Carlsbad salts. Both recovered at the end of about a year.

Third Day—July 27th.

Dr. Wm. C. Krause, of Buffalo, read a paper entitled "Observations in a Case of Myxedema." He reported a case of myxedema in a woman, fifty-three years

old, whose mother was afflicted with symptoms similar to the patient's. The patient had always been in good health up to her forty-sixth year, although she had never perspired, and the secretions, as the saliva, nasal mucus, and the milk, were always scanty. Following upon an accident, her face, body, and extremities became swollen, her hair suddenly disappeared from all parts of the body, and she suffered with severe pains, especially through the temples, and a tired feeling incapacitating her for all kinds of manual labor. She further complained of a feeling of coldness, even in midsummer. Her hands were dry, harsh, and scaly, her face waxy, and her eyes puffy and swollen. Her temperature ranged from 95.4° F. to 97.4° F. Her pulse, soft, regular, and uniform, varied from 81 to 88 per minute. The edema-like swelling did not pit on pressure. The urine was normal and did not contain albumin at any time. The only drug that acted beneficially was ferric chlorid.

Thyroid glands of sheep were given for six weeks, but no improvement whatever appeared to follow. Another case, seen in consultation, treated with desiccated thyroids, also manifested no improvement.

DR. PHILLIP COOMBS KNAPP, of Boston, read a paper entitled "Simulation in Traumatic Nervous Diseases." He said that although many persons will simulate disease if it be to their advantage, successful simulation of the various traumatic nervous affections is rare.

Non-traumatic hysteria and neurasthenia present many symptoms that appear counterfeit, the victims of these diseases often being accused of pretending to be ill, when really the malady is a serious one.

Contraction of the visual field, anesthesia, tremor, disturbances of the reflexes, circulatory disturbances, and Mannkopf's symptoms are to be regarded as important objective signs. Few simulators have intelligence enough to withstand a searching examination by a skilled neurologist.

Furthermore, a person can keep his attention fixed on any subject only for a very brief time, and if he must be prepared to defend his simulation of half a dozen different symptoms he will inevitably be tripped up by unexpected tests applied when his attention is diverted.

Three cases were cited in which the defence claimed that there was simulation, but in every case objective evidence proved the reality of the disease.

Of fifty cases in which claims for damages had been made, only two could be regarded as simulating, and few as exaggerating, and in most of these there was little reason to suspect any deliberate attempt at fraud.

DR. MILLS maintained that absolute simulation is very infrequent. The cumulative exaggeration of symptoms, however, is comparatively frequent. A few persons can simulate a type of insanity or a traumatic neurosis, but cannot easily simulate all of the symptoms and signs.

DR. GRAY said that many cases supposed to be simulating are simply offering to the trained eye symptoms indicative of possible simulation. He related a case of traumatic neurasthenia cured by $\frac{1}{125}$ grain of atropine taken for two days.

DR. LLOYD held that the symptoms of traumatic neurasthenia are nothing but the inter-paroxysmal symptoms of hysteria. Because a person develops hysteria after an accident there is no reason to believe that he must be a simulator.

DR. SEGUIN exhibited a specimen stained with a 1 to 2000 solution of nigrosin, a method that he used many years ago, but neglected to publish. One of the advantages is that specimens may be safely left in the solution for twenty-four hours.

DR. C. L. DANA, of New York, read a paper entitled "The Microbic Origin of Chorea, with a Case." He reported the case of a man, twenty-six years old, who had had chorea from the age of fifteen, the attacks appearing exactly like those of ordinary chorea. At first there were intermissions, but the disease finally became chronic. The spasmodic movements were general and violent. There was no heart-disease or rheumatism.

The patient died from exhaustion. The post-mortem examination showed microscopically a conspicuous chronic lepto-meningitis involving the vertex of the brain. Microscopically this was found to be mainly a proliferation-process, without exudation or much cell-infiltration. In the superficial layer of the cortex there were cellular infiltration and degenerative changes. At this point diplococci were found. The microörganisms were found only in the deep layer of the pia and the superficial part of the cortex.

In addition, there were found peculiar hyaline bodies in the three outer layers of the cortex and less numerously in the basal ganglia. There were evidences of meningeal irritation, vascular disease (arteritis), and nerve-root irritation in the medulla and upper part of the cord. The lower part of the cord was not examined.

The following named gentlemen were elected to active membership: Dr. Brower, of Chicago; Dr. Burr, of Philadelphia; and Dr. Diller, of Pittsburg. Dr. Arnold Pick, of Prague was, elected an associate member.

The following papers were read by title: "The Genesis of Hallucination, Illusion, and Delusion," by Dr. H. A. Tomlinson, of St. Peter, Minn. "The Diagnosis of General Paresis," by Dr. L. C. Gray, of New York. "A Report of Two Cases of Friedreich's Disease," by Dr. Frank R. Fry, of St. Louis. "The Metapore or Foramen of Magendie in Man and in the Orang," by Dr. Burt G. Wilder, of Ithaca. "Observations on the Relation of Chorea to Rheumatism," by Dr. Eugene Riggs, of St. Paul. "Experiences in the Use of Testiculin and Cerebrin," by Dr. J. J. Putnam, of Boston. "Peripheral Paralysis after Surgical Operations," by Dr. V. P. Gibney, of New York. "Traumatic Brachial Plexus Paralysis in Infants," by Dr. Wm. M. Leszynsky, of New York.

The officers elected for the ensuing year were: President, Dr. B. Sachs, of New York; Vice-Presidents, Dr. F. X. Dercum, of Philadelphia, and Dr. P. C. Knapp, of Boston; Secretary and Treasurer, Dr. G. M. Hammond, of New York; Councillors, Dr. E. C. Seguin, of New York, and Dr. J. H. Lloyd, of Philadelphia.

BRITISH MEDICAL ASSOCIATION.[1]

Sixty-first Annual Meeting, held at Newcastle-upon-Tyne, August 1, 2, 3, and 4, 1893.

FIRST DAY—AUGUST 1ST.

DR. GEORGE HARE PHILIPSON delivered the President's Address. He expressed his appreciation of the

[1] From advance proof-sheets kindly furnished by *The British Medical Journal.*

distinction conferred in being made President of the Association, and offered a hearty and cordial welcome.

The Association had previously met in Newcastle in the year 1870. In the interval of time it has greatly increased in numbers, power, and influence. At the annual meeting in 1870, 320 members attended, and the Association numbered 4258. Now it has on its roll 14,700 members. The proportion of British members of the profession who are not yet members of the Association is a steadily decreasing minority. The Association may fairly claim to have brought about for the profession throughout the British Empire the federation which still remains the dream of the politician. Medicine, happily, knows no frontiers, except such as are erected by diversity of language. Members of the Association are to be found in every quarter of the globe, and there are now but few British dominions, colonies, or dependencies in which a branch of the Association does not exist.

At the Newcastle meeting in 1870, Mr. Ernest Hart was reappointed the editor of the *British Medical Journal*. The power and ability, high professional tone, and ministerial direction which he has displayed in its conduction must be apparent to every member of the Association. The weekly issue, in the interval of nearly a quarter of a century, has been increased from 2000 to 17,500. On such a satisfactory result Mr. Hart is to be heartily congratulated. By his editorial work he has largely contributed to advance the well-being of the nation, to promote the best interests of the medical profession, and to increase the good feeling of its members.

Consideration was given to matters connected with Newcastle, historic and otherwise. The city has two institutions of a collegiate nature—the College of Medicine and the College of Science, both being colleges of the University of Durham. As early as 1834 classes were established in Newcastle for the study of medicine. In 1852 the School of Medicine was received into connection with the University of Durham, and in 1870 the affiliation was rendered more complete by the school becoming a college of the University. The lecturers of the College are officers of the University in the Faculty of Medicine, and the students are undergraduates of the same faculty. In the present College, which was opened in 1889, every modern improvement has been adopted, whereby the medical education and the well-being of the students can be furthered. In the College Calendar for 1893 the list of students is 262.

In the University of Durham, in the academic year of 1892–93, 145 degrees in medicine, surgery, and hygiene were conferred. The University was the first of the examining bodies of the United Kingdom to institute a practical examination in anatomy and chemistry, and a clinical examination in medicine and surgery for degrees in medicine and surgery. It was also the first University in England to grant degrees in hygiene. A professorship of comparative pathology has been recently founded by the University in the College of Medicine, the endowment for which was generously bequeathed by the late Dr. George Yeoman Heath, Professor of Surgery and President of the College of Medicine. Thus, through the foresight and munificence of one of its most illustrious professors, the University has become the pioneer of a new branch of medical education.

The medical institutions in Newcastle are numerous and well supported. The Royal Infirmary, established in the year 1751 for the counties of Newcastle-upon-Tyne, Northumberland, and Durham, from time to time has undergone additions, and at the present time has accommodation for 280 in-patients. The particular interest of this institution is that it exhibits the changes that have taken place in hospital-construction and arrangement during the past 150 years. Efforts are being made to obtain a new infirmary. The Newcastle Dispensary, founded in the year 1777, was the second of the kind in the provinces. The first systematic returns of the sickness of the borough appeared in its annual reports. The City Hospital for Infectious Diseases, situated at Walker, built on the single-story-pavilion system, with a disunited administrative block, is available for 100 patients. The Prudhoe Memorial Convalescent Home, at Whitby-by-the-Sea, arranged on the pavilion plan for 160 patients, was erected by public subscription in memory of Duke Algernon of Northumberland. There are also the following special hospitals: The Fleming Memorial for Sick Children, the Eye Infirmary, the Hospital for Diseases of the Chest, the Hospital for Diseases of the Throat and Ear, the Hospital for Diseases of the Skin, and the Hospital for Incurables.

The diseases that may be considered to be associated with the occupations peculiar to the locality demand a short notice. In the three northern counties of Northumberland, Durham, and Cumberland, it is estimated that about 120,000 people are employed about coal-mines. To the heated atmosphere of the coal-mine, an atmosphere often laden with dust, and to the strain thrown upon the internal organs caused by the cramped position in which miners are obliged to work, the mucous catarrhs of the respiratory and gastro-intestinal tracts, from which miners suffer, may be attributed. But there are few diseases peculiar to miners.

Anthracosis is very rare. Emphysema of the lungs does occasionally occur. The pitman's asthma is well known, but it is a much less frequent disorder now than formerly. Miners are also very exempt from nephritis, which may be attributed to the profuse perspiration which they experience while at work and to the daily ablution which they practise on their return home. Contrary to what might be expected from the violent muscular exertions necessary to hewing, and from working frequently in wet and damp places, and always more or less in currents of air, rheumatism and rheumatic fever rarely affect the coal-miner. The explanation of the exemption is the same as that given respecting nephritis. The miners of the North of England have an average of three years longer life than the aggregate of Englishmen, eight years longer than the Cornish miner, nine years longer than the South Wales miner, and only one year less than that of the men of the healthiest districts of the kingdom.

The frequent occurrence of diseases of the cardio-vascular and nervous systems is to be noted. The workers in iron, particularly the puddlers and strikers, are prone to suffer from diseases of the heart and aorta, owing to the strain thrown upon the bloodvessels. From the records of the Newcastle-upon-Tyne Royal Infirmary for the past five years of all the medical cases, 15 per cent. were of diseases of the circulatory system, and

of this number 15.6 per cent. were cases of disease of the large vessels; the pathologic changes observed were dilatation and hypertrophy of the ventricles, with incompetence of the aortic valves; and 17 per cent. were of diseases of the nervous system.

There are large lead-works on the Tyne, both of white and red lead, and the Royal Infirmary is rarely without several cases of lead-poisoning. It is observed that the women suffer much more than the men; the records of the Royal Infirmary show twice the number of women to men, as it is the former who are employed in handling and stacking the carbonate of lead. The carbonate of lead when introduced into the system by inhalation or otherwise mixes freely with the fluids, and causes a toxemia followed by convulsions, and a fatal coma termed "lead-encephalopathy." As death under these circumstances has been rapidly induced, no marked structural change is detected in the internal organs. In the more chronic cases the effects of lead-poisoning are found in structural alteration of the heart and kidneys, and central and peripheral changes in the nervous system; and lead has been found in the internal organs upon necropsy. As to the remedy for this state of things, the subject requires the most careful investigation in the interests alike of the employer and the employed.

Asiatic cholera, described as such, has been epidemic in Newcastle upon three occasions. The first visitation occurred in 1831–32, causing 322 deaths; the second in 1848–49, with 412 deaths; and the third in 1853, with 1533 deaths. The water supplied to Newcastle in 1832 and in 1853 was polluted, and in 1849 was uncontaminated. In 1849 the mortality in proportion to the population was seven times less than in 1832 and 1853.

Respecting the threatening of cholera in England in the autumn of 1892, in September, one sailor from Hamburg arrived in the Tyne suffering from the disease. He was removed to the floating hospital at Jarrow-on-Tyne, and died. There was no spread of the infection. This may be fairly attributed to the strenuous action of the Tyne Port Sanitary Authority, guided by its medical officer.

The present water of the Newcastle and Gateshead Water Company is good in quality, and is filtered before being delivered. The reservoirs of the company are capable of holding 1,827,000,000 gallons.

Few towns in the kingdom have increased in their population with the present generation as Newcastle has done. In the year 1871 the population was over 128,000, being an increase in ten years of 15 per cent.; in the year 1881 over 145,000, an increase of 11.6 per cent.; and in 1891 over 186,000, an increase of 28.2 per cent. In the census of 1891, Newcastle is exceeded in its increase only by Cardiff, which is 55.7 per cent.

Of the deaths registered in Newcastle from all causes in the ten years 1871–80, the average rate of mortality was 25.8, and in the ten years 1881–90, 23.6, a diminution of 2.2, and during the same decades, of the seven chief zymotic diseases, there was a diminution of 1.6.

Questions relating to State medicine were also taken up, especial consideration being given to the subjects of the notification of diseases, the pollution of rivers, lunacy legislation, and other matters of public health. A plea was made for a Minister of Public Health.

SECOND DAY—AUGUST 2D.

DR. DAVID DRUMMOND delivered the Address in Medicine. His subject was entitled "Causal Relations in Disease." He entered upon a consideration of some prominent morbid relations and the deductions therefrom.

To the question why etiology and treatment have lagged far behind diagnosis in the scientific race, notwithstanding the substantial impetus given by the labors of explorers in the microcosm of disease, it may be answered that it is perhaps from an insufficient consideration of the possible end to which this great principle of causation may lead, and also from a too great proneness to multiply causes unnecessarily, and at times flippantly against the protests of science and philosophy. A hint might with advantage be taken from the chapter of modern experimental pathologists, and the demonstration aimed at, that a disease can be referred with more justice to one definite cause than to several, each credited with its *pro rata* share of statistical responsibility. It will no doubt be objected that no matter how desirable such a demonstration may be, our present knowledge does not admit of it. But even if this be so, an attempt at least should be made to differentiate morbid conditions that may, by their close symptomatic resemblance to each other, be confounded, and to refer each to its proper cause.

The divergence of opinion that exists in reference to the true causal factor of some diseases may, in a measure, be due to the employment of terms that do not convey precisely the same meaning to all who use or read them. Hence, naturally, ensues a confusion that will gradually disappear as the reference or reduction of morbid conditions to their true and definite cause or origin comes to be prescribed as an ideal to be realized more and more fully with the progress of knowledge. The employment of this method will eventually lead up to the formation of a nomenclature which, in addition to being strictly accurate, may prove of immense therapeutic and diagnostic value, and guard against the mistakes incident to the habit of giving to a group of symptoms or a pathologic condition a name that may indicate a discoverer, but does not indicate the nature or origin of the disease.

An apt illustration is furnished by those numerous and seemingly distinct lesions of skin, eyes, brain, joints, lungs, etc., which aforetime were regarded as separate entities, but which are now known to have one causal factor in common, the bacillus of tubercle, linking all together. Thus the study of tubercle grows in importance as its circle of causal relations widens, and each new fact in its life-history or its manner of decay throws more light upon this great clinical family.

The persistent attempt to reduce morbid conditions to a single cause will have a material and beneficial bearing upon the method of treatment. It is agreed that a cure to be effectual must reach the root of the disease. Once let assurance be given that the true origin has been discovered, and the proper treatment, if adopted early in a remediable case, may reasonably be expected to be successful.

Another advantage to be reaped from the recognition of unal causation in morbid relations is its diagnostic

help, for if the patient's symptoms point in the direction of a possible disease which, in the experience of the practitioner, is commonly preceded by a definite causal factor, and he can assure himself of the presence of this factor, then the evidence is strengthened and the diagnosis materially confirmed. To the objection that the number of cases of striking morbid affinities are too few to be of any practical value in this direction, it may be replied that the bond of union between certain associated lesions is being daily more recognized, and that the circle of causal relations is ever widening so as to include an increasing number of diseases.

Dr. Drummond then proceeded to examine a few of the more prominent morbid conditions whose claim to belong to the category of diseases having a constant cause is pressing. In this class he included the relation between syphilis and locomotor ataxy, which from his experience he believes to be constant. He regards, and has long taught accordingly, locomotor ataxy as invariably the result of antecedent syphilis, and that (some statistics notwithstanding) where the former is found it may be declared with a feeling of absolute certainty that there has been at a previous date the latter, to which this locomotor ataxy is in some manner due.

Another disease that is to be ascribed to the same specific factor is general paralysis of the insane. Here the burden of proof is attended with still greater difficulties to the statistician, who has in many instances to deal with patients whom Nature, in robbing of past memories, has deprived of the ability, if they possessed the will, to furnish a true record. And, further, there is a larger proportion of women amongst general paralytics than amongst tabetic cases—a fact that lends an additional complication to the case. Notwithstanding these obstacles Jacobson has recently declared that at least 65 per cent. of the cases are specific, and years ago Steenberg and others contended for the unal theory, namely, that there was "no general paralysis without syphilis."

The importance of adopting this view, if it be correct, can scarcely be overestimated, for it will surely clear the way for a reliable diagnosis if it can with confidence be said that, in eliminating syphilis in a mental case one is practically excluding general paralysis—a factor that may turn the balance when, as often happens, one is compelled to catch at diagnostic straws. If further evidence were required in support of the theory of the constant connection between syphilis and general paralysis of the insane, over and above that furnished by statistics and interpreted in the light of the inductive method of reasoning, it is to be found in the fact that this disease is virtually the only progressive mental disease known to be associated with a definite and recognizable anatomic lesion. This fact alone justifies an opinion in favor of a special causation, for it singles out the disease, and seems to warrant the conclusion that, as a definite pathologic process has been at work, so has there also been a special etiologic factor.

It may be rash in the light of past failures to predict much therapeutic benefit from the recognition of the cause in the instances cited, but may it not be fairly asked: Might not the results have been different had the remedies been applied earlier? For it will not be straining to an unreasonable extent our knowledge of "specific" lesions to suggest that preceding and underlying the morbid changes of the nature of sclerotic degeneration with which all pathologists are familiar, and which, as is known, have defied our remedies, there is a stage of specific myelitis and neuritis that tends to run an extremely chronic and insidious course, and may be most difficult to recognize clinically, unless perchance a timely warning be given by a ptosis or a diplopia, etc., when the administration of suitable remedies might be expected to yield a good result. How many cases of locomotor ataxy and general paralysis have been prevented by the timely use of anti-syphilitic remedies, when at the outset a clue is forthcoming, it is impossible to say.

Dr. Drummond laid yet another sweeping accusation to the charge of this many-headed hydra, the extent of whose subtle and baneful influence seems scarcely yet realized. For many years he has been deeply interested in the study of the connection between syphilis and aneurism, and in common with others has been struck with the frequency with which the former occupied a prominent place in the history of a sacculated aneurism. The inquiry has been pursued with special care, with the result that since the commencement of the investigation no indisputable case has come under notice in which specific disease was wanting, excepting two or three examples of that interesting condition, acute softening of the arterial wall, with aneurismal bulging, in malignant endocarditis. In order to emphasize this statement it was pointed out that the observations applied to a part of the country in which aneurism is an exceedingly common disease; during the past ten years 145 cases of aneurism of the thoracic aorta have been treated in the wards of the Royal Infirmary.

No attempt was made to establish the specific character of the aneurismal process, and it was not denied that sacculated arterial bulging to the extent worthy of the name of aneurism may occur in conditions other than those due to syphilis of the arterial coats; but it was suggested that there is something special in this form of arteritis that renders the affected part of the vessel peculiarly liable to yield to pressure. It may be that the involvement of the middle and outer coats, and their transformation into fibrous tissue, so common in syphilis, will account for this liability; and it has been found a good practical rule not to diagnosticate aneurism in a doubtful case in the absence of syphilis—a rule that must be more or less limited in its application, as it necessarily presupposes an accurate history. Arterial strain through hard work, is of course, a factor in the production of aneurism, but it is one that in the vast majority of instances requires to be multiplied by specific arteritis in order that the product be aneurism, and then it is the lesser quantity of the two.

The causal relation of pneumonia to empyema, one of the closest if not the most constant, the latest textbooks notwithstanding, is another exemplification of the subject. True there are cases of pus in the pleural cavity that have not arisen out of an attack of pleuro-pneumonia, due possibly to an acute septic pleurisy, or to tuberculous pneumothorax, or as the result of a simple effusion becoming contaminated by septic matter, say by means of a trocar, but these are exceptions. Exclude them, and it may fairly be concluded that empyema, the common disease with which practitioners

are so familiar, may be ascribed to an antecedent pneumonia. It is of the greatest moment to recognize an empyema as early as possible, for the sooner the pus is evacuated the shorter will be the surgical treatment of the case, and the better the prospect of permanent recovery; and, further, if taken very early, a single tapping without incision and drainage may effect a cure. Now the diagnosis of these cases turns largely upon the discovery of the pneumonic factor; in other words, familiarity with the fact that effusion following pneumonia is very likely to be purulent furnishes a clue to diagnosis.

Few subjects have excited more interest than the relation between rheumatism and chorea, and none has occasioned greater divergence of opinion. The discrepancy relates chiefly to the question of degree, for nearly all allow a certain affinity between the two diseases. If it be admitted that a certain proportion of cases of chorea are associated with rheumatism, the inquiry naturally divides itself into two parts, the nature and extent of the relationship. Clinical observation indicates that in a certain proportion of cases, at least, chorea is simply one manifestation of the disturbance by the rheumatic poison of the function of somewhat unstable and growing cortical cells; and if this conception be tenable in a few instances, may it not be extended so as to include the whole of the familiar group of typical choreic cases so common among the children of nervous and rheumatic families, and prone to yield to large doses of arsenic? The study of cardiac lesions throws into relief the importance of tracing diseases to their true causes. They are all referable to primary conditions—rheumatism, gout, specific fevers, tuberculosis, sepsis, alcoholic excess, syphilis, etc.—which are singularly fruitful in morbid products. These conditions constitute a formidable list, to which additions are constantly being made, and each is responsible for heart-affections having more or less characteristic clinical and pathologic features. The immense importance of investigating cardiac diseases upon the basis of their antecedent and underlying morbid states cannot be overestimated, for the treatment and prognosis depend largely upon the particular agent at work. The same remark holds good in the case of lesions of other organs, a fact that in many instances has been fully recognized; but, its application in heart-disease is perhaps more than ordinarily conspicuous. It has been the habit of the schools to attach too much value to the diagnosis of the particular valve-lesion, and too little to its cause. Thus, for example, we content ourselves with the shallow and often unimportant observation that this or that case is one of mitral regurgitation or double aortic disease, a diagnostic shibboleth that any novice may apply; forgetful that what is of paramount importance is not only the primary reason for the existence of the lesion, but also the cause upon which the symptoms belonging to any subsequent attack of cardiac failure may depend. Thus the inquiry would necessarily embrace the questions, in the case of toxemic lesions—gouty, rheumatic, alcoholic, etc.: Is the poison still circulating? and what is the prospect of its return? Difficult and at present more or less problematic are these questions, but to them we must direct our attention before we can hope to prognosticate and treat heart-disease successfully.

An attack of rheumatism may damage a valve and leave behind a permanent legacy, but how innocuous that structural change may be, so far as the health of the patient is concerned, so long as his real enemy—rheumatic poison—remains absent, is well known to all practitioners. For there can be no doubt that the injured endocardium is very likely to suffer further damage under the influence of fresh rheumatic attacks, however slight. It is these intercurrent rheumatic accessions, often subtle and unattended by any outward manifestation beyond fever, that are fraught with so much risk. So, also, is the case of gouty mischief, but here the causal factor is more constant and insidious in its operations, and its ravages are too often deeply rooted before they are recognized, a fact that should lead to greater diligence in unearthing a latency so dangerous.

In syphilis we have a much more common cause of heart-disease than the text-books admit, and surely a morbid agent that might be met and treated if recognized at the outset; but how seldom has the attempt been made, though specific arterio-sclerosis is an obvious pathologic entity.

The varieties of alcoholic heart-disease are now receiving attention, and, with increasing clinical and pathologic information, it is to be hoped that fewer mistakes in prognosis will be made; for often the alcoholic heart fails suddenly, giving rise to an unexpected catastrophe, despite the most favorable prognosis, because the mischief, being rather of the myocardium than of the valves, has remained undetected.

Careful attention to these etiologic circumstances will often enable us to help the poor cardiac backslider in a more substantial way than if we simply consider his defective machinery and treat his more pressing wants, regarding the intercurrent attacks as natural and unavoidable incidents in the course of the disorder. It has at times been possible to demonstrate in the post-mortem room that the valve-lesion from which the patient had suffered was due to a chronic tuberculosis of the pericardium resulting in general adhesions, and that the valves supposed to be diseased were in themselves healthy, though the orifices were dilated and the myocardium degenerated. Obviously the treatment and prognosis of such a case must differ from the treatment and prognosis of cardiac failure from pericardial adhesions, or of a heart damaged in early life by scarlatinal valvulitis and broken down by excessive work, or of a rheumatic case marked by returning and often protracted pyrexial attacks, or of an insufficiency directly due to alcohol.

A substantial reduction in the number of chronic heart-cases, as the result of the recognition of the fact that many are due to curable and preventable causes, which an early and successful treatment might reasonably be expected to subdue, would not be a dream too visionary for us to indulge in; but assuredly until the causes are fully appreciated, a dream it will remain.

It would be difficult to select a better illustration of the benefits that have arisen from the influence exercised by the view that the true or ultimate causes underlying diseased states are, in the botanic sense, solitary, and that the paths along which they travel are comparatively few and well-beaten, than the knowledge that guides advanced surgeons in their dealing with suppurative peritonitis—the knowledge, namely, that these cases always result from infection of the peritoneum with pus-

microbes. Pathologists have helped their surgical friends to give a practical turn to this fact by recognizing that the infective microbes gain an entrance either by perforation of a viscus — ulcerated appendix, bowel, or stomach — or the rupture of a puerperal abscess, a generalization that serves a useful turn in practice, though scientifically speaking it may not be quite accurate.

An extension of this line of thought cannot fail to bring conviction that the nosologic tables hardly contain the name of a systemic disease that is not simply the reflection of some primary morbid state with which we are more or less familiar. Many of these, it is true, are known only as subtle influences, but they are becoming rapidly less shadowy, and before long it is to be hoped that the bright light begotten of the fierce competition and zealous spirit of work so characteristic of the present day will reveal their true nature. At present, like light itself, they are not understood, and are scarcely discernible, until by falling upon some organ with whose form and functions we are familiar, they are reflected to the eye of our understanding.

Consideration was given to some possibilities in the modifying or controlling influence exercised by one disease upon another.

The proposition was made that familiar clinical pictures of disease of an organ are often the product of the symptoms peculiar to it, and of others which are the expression of impaired function of another organ. In other words, the full symptom-complex of disease of one organ may be largely contributed to by disease of another, whether produced by the same or some other cause. For instance, a patient addicted to alcoholic excess for a considerable number of years is known to be suffering from a group of dyspeptic symptoms, ascribed by the patient, friends, and doctor to this cause, but without a suspicion of gross organic mischief underlying them. This state of health interfered but slightly with the discharge of public and private duties, and indeed, beyond loss of flesh and some discomfort, there was a complete absence of signs of disease. An attack of pneumonia, which tried his powers of endurance considerably and was followed by a slow convalescence, completely altered the character of the case. Within a fortnight or three weeks of the incidence of the pulmonary disorder the abdomen swelled and its superficial veins enlarged, the lips became red and the tongue glazed and red, the face pinched and the urine scanty and full of urates, the motions black, and in every way a most suggestive picture of cirrhosis of the liver was presented, a transformation that astonished the doctor and friends, and was not at first sight easily explained. The only reasonable assumption to account for the apparently rapid delevopment of cirrhosis of the liver was that the disease had existed for a considerable period in a latent form, and that the obstructed portal circulation was compensated for by the usual auxiliary relief, which served to reduce congestion, and thus keep in check the tendency to ascites, etc., until the attack of pneumonia, by producing cardiac insufficiency, upset the balance, and led to the appearance of the typical signs hitherto absent. Though the pathologic changes characteristic of cirrhosis were present, the clinical aspect of the case was incomplete until a new and necessary factor, which had nothing to do with the original disorder, revealed the true nature of the illness. It seems a just inference that the cardiac affection made an important, if not essential, contribution to the completion of the symptoms picture. There is reason to think that in cirrhosis of the liver generally the occurrence of the abdominal dropsy largely depends upon the supervention of heart weakness. It is not unusual for the dropsy of chronic nephritis to be determined by heart-weakness.

It is not enough to say that clinical pictures may be the joint products of symptomatic morbid relations, for they are often presented under the modifying influence of a tendency or bias, lent by a former or a concurrent disease; that is to say, it is quite common to meet with pronounced modifications in the clinical pictures of disease which can only be accounted for on the principle that one disease has a determining influence upon the aspect of another. Thus, a young man, aged twenty-two, suffered in the autumn of 1891 from an attack of alcoholic paralysis which revealed itself in the usual form of weakness in the legs, flapping of the feet in walking, with, eventually, ankle-drop and paralysis, and paresis of the extensors of the fingers, along with which were severe myalgic pains. He recovered satisfactorily, and at the end of four months he was able to walk, and a little later to ride his bicycle. In May of the following year he had an attack of diphtheria, and in a few weeks, while strictly temperate, he developed, without any defect of sight or impairment of swallowing, numbness and weakness of the legs and hands, and indeed a very similar condition to that which had existed previously, except that the pains were absent. In this case the diphtheric palsy was exhibited in a somewhat unusual form, in consequence of a predisposition to a special paralytic distribution lent by an attack of alcoholic neuritis. Cases of diphtheric paralysis are met with in which the lower extremities bear the brunt of the poison, but it is exceptional to meet with so pronounced a paraplegia in the entire absence of the usual signs, such as failure of accommodation, dysphagia, etc.

In another instance a man in the prime of life, who was much addicted to alcohol, came under observation for complete double wrist-drop, presenting every feature of a plumbic case. His history revealed the fact that twelve years previously he had suffered from lead-palsy, with blue line, the result of drinking contaminated water, and as he was recovering he acquired intemperate habits, and developed into a chronic toper. The consequence was that the paralysis of the extensors became more pronounced, and remained permanent. There was absolutely no paralysis of the lower extremities, and the knee-jerk was normal.

The modifying influence of one lesion upon another may be, as it is well known, decidedly beneficial. Thus, sarcoma and lupus may yield to the poison of erysipelas; of which fact, it is reasonable to suppose, more will be made in the immediate future.

The controlling effect of disease on disease is also to be seen in the fact that it is quite rare for pulmonary tuberculosis to spring up in the course of a cardiac affection. Again, it is not unusual when lardaceous disease develops in consequence of chronic pulmonary tuberculosis, to observe a distinct tendency on the part of the tubercle to be arrested in its growth. Further, in

this connection the rareness is striking with which a pneumonia complicated with jaundice proves fatal.

THIRD DAY—AUGUST 3D.

DR. G. H. HUME delivered the Address in Surgery, taking as his subject "The Evolution of Surgical Principles."

The mode of growth of scientific principles can find no better illustration than in our modern doctrines of surgical repair. The beginnings of these doctrines may be traced far back in the history of surgery. Hunter's statement that "primary healing takes place without inflammation" contains the germ of what we believe and act upon now. It did not, of course, go far enough. It defined the relationship between what was then, as it is now, ideal healing and inflammation, in the sense that no relationship can or does exist between them at all. There is, however, no such definite expression to be found in Hunter's writings with regard to the modes of secondary healing. Hunter believed, as did most of his successors down to the last few years, that a certain degree of inflammation was necessary for these delayed forms of healing. Indeed, from Hunter's time there was a falling away from the faith, and the most philosophic surgical opinion, as represented by Travers, held that a "subdued state of inflammation favors healing," and that to "supersede it would effectually retard or preclude" the process of repair.

Down to a recent period the ideas of healing and the ideas of inflammation seemed in the very nature of things to be inseparably interwoven. It turns out that they were only needlessly entangled, and ideas which in the time of their confusion belonged mainly to the region of theory have since proved to be matters of the most eminent practical importance. The process of disentangling began in and proceeded with the elucidation of the true nature of inflammation and its consequent suppuration. There was a time when the four classical symptoms of pain, heat, redness, and swelling, summed up nearly all that was known of the process of inflammation. Then followed the anatomic era, the time most fruitful of bewilderment to the student, in which, thanks to rapid improvement in the methods of microscopic investigation, attention was concentrated upon the blood-stasis, the changes in the tissues and in the vessel-walls, and on the out-wandering of the colorless corpuscles. An intermediate stage followed this in which, clinically and experimentally, the suppurative processes were recognized to be infective in nature. This culminated in the present period in which the whole process is demonstrated to be due to the agency of microörganisms. One point, however, remains to be cleared up. Is the febrile access which follows an aseptic operation, sometimes sharp in degree though short in duration, to be looked on as the result of inflammation? There is no ground for supposing it to be an infective process, the same in kind and differing only in degree from that which always tends to suppuration. If different in nature it should also be distinguished in name, and there is much to justify the proposal to restrict the word inflammation to those changes that result from the action of septic organisms, while the other and simpler process under some such title as traumatic reaction demands further examination for the clearing up of its intimate character. Such a defined use of the term would end the confusion which has hitherto attended the conception of inflammation as a disease, and would rest on the sure ground of etiology the idea to which the word corresponds.

Naturally with the true knowledge of inflammation and suppuration have come clearer and more accurate views with regard to the process of repair. Not alone in primary adhesion but in all forms of healing it is seen that inflammation is never a help, and can only be a hindrance, and that if it occurs repair must take place in spite of it, or be delayed until it has passed away. The surgeon's part, therefore, is not to treat but to prevent inflammation and suppuration, and the practical side of the scientific evolution that has taken place is the antiseptic system.

It has sometimes been made a reproach against the system of wound-treatment by the introduction of which Lister created an epoch in surgery that its methods and details have undergone constant change. But through all the alterations of detail that the desire for greater simplicity or increased security has prompted, there has been no deviation of principle. The dependence of suppuration and septic diseases upon organisms, and the prevention of these diseases by destroying or getting rid of the cause, constitute the principle on which the treatment rests, and it is one that admits of some latitude in its application. The aim can be achieved in two ways. Either reliance is placed mainly on the germicidal powers of chemical agents, or the surgeon prefers to trust rather to the removal of the minute organisms along with the soil in which they flourish. The two roads to the same end are known under the names antiseptic and aseptic; and, fortunately, both can be travelled on at the same time. It has been thoroughly learned that cleanliness takes no second place, but it is the highest virtue in surgery. Therefore no pains are spared to remove every particle of dirt from the area and all the accessories of an operation; and in addition the further security is obtained which the use of some germ-destroying agent can give.

The main changes in the technique of the antiseptic treatment have owed their origin to changing views as to the sources whence danger of infection might be expected to arise. Under the guidance of his earlier experiments, and in accord with the work of Pasteur and the investigations of Tyndall on the floating matter of the air, Lister devised his measures for the avoidance of atmospheric contamination; hence at first wounds were sealed, and later the spray was employed. Gradually the belief strengthened that the air as a source of danger might practically be neglected, and the spray was given up, with a sigh of relief. It had come to be admitted that the surgeon's hands and the skin of the patient, besides the instruments and sponges which had always been cared for, were most often at fault; and as a result even the most orthodox believers in the potency of carbolic acid or corrosive sublimate became scrupulous cleansers.

The antiseptic system admits of latitude in its application; it is open to everyone to elaborate his own technique. The worst surgery, indeed, is the stereotyped surgery; the best is that which, working faithfully from sound principles as a science, encourages as an art fertility and variety in their application. But with whatever variety of method, there ought to be now no grades in the standard of work sought to be accomplished. An

ideal of healing that was occasionally attainable by the many, or more consistently reached by the few as the result of fortunate circumstances or the reward of strenuous care, has become a generally accepted obligation. No one now is ever heard to speak of laudable pus; no pus is considered praiseworthy; but, on the contrary, if it appear in a wound for which the surgeon is responsible, and in making which he had the control of all the conditions, it is always a thing to be ashamed of. Healing without suppuration, therefore, is the end aimed at in all operation-wounds, and in a sense it is an extended description of union by first intention. It applies to wounds healing by granulation, or by the organization of a blood-clot, as well as to those uniting by primary adhesion. For all alike Hunter's description holds good: "If a wound heals by first intention all keeps quiet as if nothing had happened." As Von Volkmann, one of the most distinguished and thorough of the German followers of Lister, puts it: "A primary healing wound several days after the operation ought to look exactly as if it had just been stitched; no swelling and redness; no heat; no pain."

From trusting more, because knowing better, Nature's powers of repair, it has followed that the range of reparative surgery has been greatly widened. It is not now thought sufficient in bringing wounds together to pass our sutures through all the tissues at once, but each layer is separately stitched—muscle to muscle, fascia to fascia, skin to skin. This is one of the lessons which, if it did not at first teach us, abdominal surgery has been forward to utilize. The gain in abdominal operations is in a greatly strengthened cicatrix and the avoidance of ventral hernia. In general surgery the gain is in promoting healing by the obliteration of "dead spaces," and the consequent less frequent need of drainage. That the ends of divided muscle, if brought accurately together, will be reunited by proper muscle-tissue, and not by interposed connective tissue, as was formerly supposed, is a fact of recent acquisition, but of some practical importance. In operations on the abdominal wall—especially in certain operations for the radical cure of hernia, in which, as in Halsted's, the muscular layers are freely divided, their unimpaired reunion is essential for the success of the operation. It is necessary, therefore, that the muscles should be cleanly incised, and not haggled, and that they be afterward exactly sutured; and the cases in which such plans of operating are the least likely to result successfully are those in which the repair of so complex a structure as muscle is interferred with by suppuration.

Skin-grafting, according to the method of M. Reverdin, has long been a valued resource in hastening the cicatrization of granulating surfaces. But the method known by the name of Thiersch makes larger demands on tissue-vitality, and is of wider usefulness. When a portion of the skin—it may be as large as an inch square—is detached and transferred to a recent and aseptic wound, it retains its inherent vitality until it becomes penetrated by bloodvessels advancing into it from its new bed. It is thus fully adopted and incorporated in its new position. In its practical application the whole of a large open wound can be covered by this method of skin-grafting, so that the wound shall heal by first intention. The size of the area that can be so dealt with is only limited by the possibility of obtaining grafts, which may be taken either from the same or another individual, or from a quite recently amputated limb. It is not necessary in removing the graft to take the whole thickness of the true skin. A portion of the corium left behind will, by obviating cicatricial contraction, lessen the sacrifice for that surface which is the donor, without diminishing the value of the gift to the recipient. In plastic operations on the face, and in operations for malignant disease which have involved free removal of skin, the method has found useful application. In cases of chronic ulcer of the leg, than which no class of minor surgical ailments gives more trouble in treatment, or more certain disappointment as to relapses, Thiersch's grafting holds out a welcome hope of cure. Bearing in mind the necessity of an aseptic condition of the bed upon which the grafts are to be placed, it is requisite, by paring the edges, and by thorough scraping of the surface with the sharp spoon, as well as by the use of antiseptic solutions, to surgically cleanse the ulcer. To get rid of the irritating effects of the antiseptics, they should be washed away by sterilized water before the application of the grafts. So treated, an ulcer is brought into the condition of a recently made wound, and success entirely depends on the thoroughness with which this transformation can be effected.

In the grafting and reimplantation of bone the incorporation takes place, no doubt, in the same manner as in the case of the skin. The breaking up of the bone into small chips is not always necessary; at least in the case of the discs removed in trephining the skull. Provided these be of moderate size, they can be replaced whole.

The process of repair in nerves is still imperfectly understood. The whole subject calls for further investigation; much also would be gained by greater and more explicit detail in the records of cases.

The history of the pathology of tubercle is divided into periods that correspond to those in the history of inflammation. There was the period of physical form, when the name was given to whatever was a tubercle in feel and outline; there was the period of minute anatomy, when the disease consisted of special cells and cell-groupings; and there is now the period which, as in it we have learned the essential cause of the disease, may be called the stage of real knowledge.

Before the microbic origin of tubercle was known surgery was becoming more aggressive in the treatment of so-called scrofulous disease. Scrofulous glands, for instance, were excised many years ago, at first against the protest of those whose minds were wholly influenced by the supposed constitutional origin of the complaint. The surgery of strumous joints also had long been both more conservative and more successful. But from the new light the surgery of tubercle has gained immense encouragement. The commencement of the disease in a locally-infected area has modified and restricted the conception of a constitutional tendency. The constitutional origin has been changed into a constitutional vulnerability; and, undeterred now by an idea that weighed upon him just in proportion to its vagueness, the surgeon undertakes the treatment of local manifestations of tubercle by local measures. In consequence the surgery of tubercle has undergone great extension. Affections of the skin, of the glands, of the bones and

joints, of the urinary organs, of the peritoneum, wherever the disease can be reached and wholly removed, or its action favorably modified, it is submitted to local treatment. The extension has been in the direction not only of new applications, but of greater thoroughness. The knowledge of the infective character of the disease and of the liability to local relapses, or even general infection as a consequence of incomplete removal, has led, for example, to the excision of every affected gland or of every diseased focus in a joint. The guidance afforded by pathologic knowledge is even more explicit with regard to other points of treatment. The important question of general infection has light thrown upon it by what we know of Nature's endeavors to imprison a tuberculous focus by a wall of granulation-tissue. When by an incomplete operation we break down this wall or cause it to crumble by infecting it with pus-microbes, without entirely removing the tuberculous disease, we open the way for the passage of the tubercle-bacilli into the system. Hence the extreme necessity of keeping our operations free from sepsis, as well as of making them thorough. The success of the treatment of cold abscesses by evacuation, scraping and flushing, and closure of the incision—the method known by the name of Mr. Barker—is only intelligible when their true pathology is known.

The substitution of arthrectomy for formal excision has its motive in the removal of all diseased foci and surfaces, with the least possible interference with the integrity of the limb. Its occasional failures to effect lasting cure are explained by the readiness with which scraps of diseased tissue or tuberculous foci in the bone may be left behind.

The whole disease-picture presented by carcinoma offers so many points of resemblance to that of tubercle that the probability of a parasitic origin of it also has at present taken strong possession of the minds of pathologists. The occurrence of minute organisms of the class of sporozoaria in connection with carcinoma may be held to be demonstrated; but any causal relationship between them and the disease has not been proved. On one point of importance there is agreement and a growing readiness to act upon it. Due largely to the influence of Mr. Jonathan Hutchinson, a precarcinomatous stage is recognized; and it follows from the recognition that surgery ought to interfere during this period of suspicion. Another point of practical moment is brought out by the observations of Dr. Sims Woodhead and Mr. Harold Stiles on the channels of lymphatic infection. It is shown that whenever irritative or effete material has to be dealt with in large amount a special filtering tissue is developed. This, which consists of a growth of adenoid material, is formed in the connective tissue along the lymph-channels, and is produced still more strikingly by the transformation of the small lobules of fat in the axilla. One of the great difficulties of dealing with carcinomatous disease is that we have no means of knowing when lymphatic infection first takes place. As the lymph-circulation is always going on there is no reason why infection may not occur in the very earliest stage of the primary growth. If we are to trust cases of removal of the original carcinoma with no subsequent recurrence—that is, cases of cure—it may never occur at all. We do know that the infection may lie dormant for months or even years before it gives any gross indication of its presence. In dealing with it, therefore, we are meeting an enemy whose first invasion is invisible, and whose strength at any time we cannot even guess at; but all we know of its nature—both the old knowledge and the new—only points to the necessity of free removal. It indicates the removal of the next group of glands along with the primary carcinoma, whether they show gross enlargement or not; and when an operation-wound for excision of the breast and clearing out of the axilla can be healed by first intention under one dressing there should be the less objection to extensive operations for malignant disease, if only some additional security can be gained. The rules, then, enjoining early and free removal, and their application also to recurrences, so long as these are removable, are the broad principles which surgeons accept in dealing with malignant disease; they are the results of experience, and are confirmed rather than in the first instance dictated by scientific knowledge.

It is infrequent now that from topographic anatomy comes any suggestion for a fresh advance in surgery. But now and again a corrected misrepresentation or reading of anatomic facts, a new point of view or hitherto unthought-of relationship will lead to a change in surgical practice. In illustration, the rapid creation of the surgery of the cecum and appendix, in part under the impetus of the general development of abdominal surgery, still more as the rational outcome of that corrected view of the anatomy of the parts with which we associate the name of Mr. Treves was pointed out. A yet more striking instance of a change in procedure, abrupt as a revolution, effected from the anatomic standpoint, is the revival in our time of the high operation for stone. The new facility in its performance afforded by the use of the rectal bag along with distention of the bladder—again, the bias given by the growing interest in abdominal surgery, and the tendency in the present day to prefer open operations in which the parts dealt with lie well exposed to both hand and eye—all these contributed to the rapid adoption of the change.

The question of amputation in senile and diabetic gangrene of the foot seems to be in course of settlement in favor of operation. The condition is almost certainly fatal, and is fatal often after a period of lingering and intense suffering. As a measure for its relief or for the saving of life, amputation has almost uniformly failed when it has been done in the lower part of the leg. The gangrene seizes upon the flaps, and if the limb be reamputated higher up the stump is again attacked. But it has been found that if the leg be taken off in the first instance above the knee a fair proportion of cases recover. About one-half, according to the most recently collected figures, have been successful, and in a condition so hopeless and usually so painful, such a result is better than the certain issue of non-interference. Experience thus favors the establishment of the surgical canon: In spreading gangrene of the foot, amputate through the thigh.

An old and familiar surgical canon formulated by our predecessors as the result of experience, enjoined on the surgeon the duty of operating, "when in doubt," in all cases of hernia. We greatly need the guidance of some equally definite rule in cases of internal obstruction.

Upon the question of operation surgeons are, if not divided into two parties, at least biased in contrary directions. Some would operate in all cases of complete obstruction so soon as they have the opportunity; others would try other measures, see what Nature will do, and operate as a last resource. Strong arguments are to be found on either side. The surgeon who would always operate, and had always an early opportunity of doing so, would unquestionably achieve the best results possible, although he would operate on a certain proportion of cases that could spontaneously recover. Unfortunately no one is brought in contact with even the majority of his cases in an early stage. Hence arises the force of the contrary arguments. The circumstances that militate against the success of operation for internal obstruction in the fully established or later stages of the complaint are twofold. In the first place, in nearly all cases secondary changes speedily ensue, which hinder the search for the obstructing cause, and which may nullify attempts at its removal. In the second place, the patient often passes, it may be at an early period, into a condition mainly due to poisoned blood in which he trembles on the brink of collapse, and in which operation is badly borne. Add to these the fact that a not inconsiderable number of cases, even when there is stercoraceous vomiting, do recover, whose chance of recovery would disappear under the shock of an operation; and we have a fair statement of the reasoning against operating in all cases. Where are we to look for guidance? Mainly, the question must be settled by experience, which brings the ability better to discriminate between the different causes producing obstruction, and to appreciate the prognosis to be attached to each. In a syllabus of intestinal surgery recently published by Dr. Byron Robinson a list of eleven different causes of intestinal obstruction is tabulated. When we have learned more accurately to distinguish between these at the bedside we shall be much nearer to the acknowledgment of a surgical canon or rule to guide our interference.

The magnitude of many modern operations carrying surgical interference to the verge of what the human body can sustain make it more and more incumbent on the surgeon to avoid, or as far as possible to minimize, shock. We do not know the exact pathology of the condition; probably several different conditions are included under the name. But we are very familiar with its symptoms. We know that the patient becomes cold, that the heart's action is depressed, and that all the nervous functions are lowered. We know also that it is induced or aggravated by prolonged operation, by chilling of the surface, by hemorrhage, whether this take place rapidly or by continuous oozing in small quantity for a long time. The giving of chloroform on successive days also lowers the patient's resisting-power. All this supplies hints enough for its prevention and treatment. Something can be done in anticipation of the operation in the way of propping both the physical and moral courage of the patient. Much can be done after the operation in rallying from the condition; and a very small, stimulating hypodermatic dose of morphin has proved then of greater use than the same measure employed as a prophylactic. Transfusion with a normal saline solution has so wonderful a power of rallying from shock, though its good effect has been disappointingly transitory, that its use will now not be neglected. But most is in our power in the way of prevention by guarding our patients against all those causes that produce shock or aggravate it; and, therefore, the surgical canon which in this matter claims not formal acknowledgment but systematic observance is, avoid or as far as possible minimize shock.

(To be concluded.)

SELECTIONS.

ABUSE OF MEDICAL CHARITIES.

Here in London, after about a quarter of a century of agitation, and after innumerable confessions of gross abuse by the most competent authorities on the subject, no attempt whatever is being made to formulate any plan by which that abuse may be checked, and if any reflection is made in the journals on hospitals where out-patients are received out of the streets in thousands without any pretence of inquiry, the staff of those hospitals rush to the defence of the system.

Meanwhile, the numbers of out-patients are growing, and so is the pecuniary embarrassment of the hospitals, Mr. Yerbury, a member of the Distribution Committee of the Saturday Fund, writes to the *Times* of July 14th to make an earnest appeal for the Fund, and points out in his letter that the "number of new out-patients" is 1,132,433, carefully distinguishing between that number and the number of visits. He also points out that "one noble institution has been compelled to close 140 beds and another 30 for want of funds."

Now, no one can regret more than we do the embarrassments of our hospitals; nowhere does any effort to mitigate them obtain more cordial support than in this *Journal*. So we have no fear of being charged with being an enemy to the hospitals if we tell them the truth. And it is the truth admitted by their warmest friends and supporters that the out-patient system is a blot upon their fame, and that some united effort for its amendment will soon be insisted on by public opinion. That amendment must take the form of regulations to exclude both persons able to pay for advice and also persons unlikely to derive benefit from hospital treatment, and whose ailments require home treatment and supervision. We had looked with hope to the inquiry recently instituted by the Lords' Committee to lay the foundation of that reform. It seems only too likely that all such hopes will be frustrated, and that the reform must spring from the public and from the profession. But these must act through some agency.—*The British Medical Journal.*

CONSULTATION WITH HOMEOPATHS.

Mr. Hart does not realize that the profession in America has the same view as in England concerning consultation with homeopaths.

He says: "How can we expect to enter into consultation with one whom we believe to be possibly practising an honest delusion, and yet with whom we must accept the position of a mere solver of riddles?"

The agitation on this point has long since gone by. Here is the question for which the new code men strive:

May a regular go with a homeopath to see a patient, or may the latter bring the patient to his office, if the patient is treated according to rational medicine?

It is fair to conclude that when a homeopath needs a regular he needs him badly or he would not call him, and, "as the good of the patient is the sole object in view," this is a strong argument on the part of the new code men. In the nature of things it appears difficult to frame in words the meaning of this; certainly the Committee on Revision does not put it clearly. And until the new code men say just what they mean, it might be as well to keep to the old code; or, if they can't say what they mean, and this is best for medicine and the people, then let us have no written code for contention. We want to know next year, at San Francisco, intelligibly, just what we are voting on.—*Omaha Clinic.*

NEWS ITEMS.

The Pan-American Medical Congress.—Program of the Section on Pathology.

One session will be devoted to a formal discussion on the subject of "Carcinoma," to be opened by Dr. Wernicke, of Buenos Ayres, as referee, and Prof. Allen J. Smith, of Galveston, as co-referee. Papers on this subject have been promised by Dr. Joshua M. Van Cott, Honorary President of the Section, and Dr. Joseph McFarland, of the Advisory Council.

Another session will be devoted to "Yellow Fever," the discussion to be opened by Drs. Acosta and Grande, of Havana, Cuba, and as co-referee, Dr. A. J. Amades, of Puerto Rico, Honorary President.

Dr. James E. Reeves, of Chattanooga, of the Advisory Council, will give a practical demonstration of the methods in "Pathologic Histology."

Dr. Wm. M. Gray, of the Army Medical Museum, will give a practical demonstration of the methods in "Photography Applied to Pathology."

Dr. J. J. Kinyoun, P. A. Surg. U. S. Marine-Hospital Service, will give a practical demonstration of "Methods in Bacteriology.

The following papers have been promised: "Notes on Three Years' Work in the Pathologic Laboratory of the Charity Hospital of New Orleans," by Dr. Henry Dickson Bruns, of New Orleans; "Medical Geography of Puerto Rico," by Dr. A. J. Amades, of Puerto Rico; "Theories of Inflammation," by Dr. Jose Torres Matos, of Havana; on "Inflammation," by Dr. E. O. Shakespeare, of Philadelphia; on "Cholera," Dr. Herman M. Briggs, of New York; "L'Etat Hyperexcitabilité du Nerf Phrénique, dans le Beriberi," by Dr. J. B. de Lacerda, of Rio de Janeiro; "Paludismo," by Dr. A. J. Amades, of Puerto Rico; "Bacteriologic Observations on the Waters of the Harbor of Havana," by Drs. Acosta and Grande; "Observations on Malaria," by Drs. Coronado and Madau; "Operations of the Anti-rabic Laboratory in Havana," by Dr. Acosta; "Abscess of the Liver," by Dr. James E. Reeves, of Chattanooga; on "Influenza," by Dr. Ramon Guitéras, of New York; "Observations on the Brains of Feeble-minded Children," by Dr. Henry W. Cattell, of Philadelphia; and "Pathology of Pelvic Inflammatory Trouble," by Dr. Joseph Price, of Philadelphia.

Papers have also been promised by Prof. Wm. H. Welch, of Baltimore; by Dr. W. T. Councilman, of Boston; by Dr. G. F. H. Nuttall, of Baltimore; and Drs. William E. Hughes and W. S. Carter, of Philadelphia.

Prizes for Nurses.—The *British Medical Journal* announces that two prizes, one of $75 and another of $25, are offered by the editor of the *Hospital*, London, for the best two plans for a model nurses' home and training school. The competition is open to women superintendents, matrons, and nurses in the British Empire, the United States, and the countries of Europe. Descriptions must be type-written and consist of two parts: (1) a statement setting forth categorically all the rooms and accommodations which are necessary in order to make the proposed nurses' home a model of what such an establishment should be where room is provided for from 50 to 100 nurses; (2) a second statement and plan prepared in similar form which provides accommodation for from 150 to 200 nurses. Each of these specifications must be accompanied by plans drawn to a uniform scale and must explain how the proposed home for nurses can be extended, should the growth of the establishment render such a step necessary. Competitors must send their names and addresses by November 1, 1893, to Dr. J. S. Billings, United States Army, Washington, D. C., and all plans and proposals presented for competition must reach Dr. Billings not later than January 1, 1894. Dr. Billings, Dr. Henry M. Hurd, Superintendent of the Johns Hopkins Hospital, Baltimore, Md., and Miss Sophia S. Palmer, Superintendent of the Garfield Hospital, Washington, D. C., are to be the judges of the papers and plans submitted, and their decision will be final. All proposals must be type-written, on one side of the paper only, and all plans must be drawn to a uniform scale of ⅛ inch to 1 foot. It is proposed to publish an account of the competition, with a selection from the competing plans, such publication to be undertaken by the *Scientific Press*, London, at their option, to whom papers and plans will be sent by the judges after they have made their award.

A Case of Cholera in New York Harbor.—It is officially announced that a case of cholera has been found among the passengers of the steamer Karamania, which left Marseilles on July 15 and Naples on July 22. The diagnosis was based upon the detection of cholera-bacilli in the intestinal evacuations. The patient had been isolated on Swinburne Island, and is recovering. All of the other passengers are in good health. There is no fear of a spread of the disease.

The International Medical Congress Postponed.—Dr. A. Jacobi, Chairman of the American National Committee of the Eleventh International Medical Congress which was to meet in Rome, Italy, September 24 to October 1, 1893, has received a cablegram that the meeting of the Congress has been postponed to April, 1894.

The Medical Society of Virginia will hold its twenty-fourth annual session at Charlottesville, Va., October 3, 4, and 5, 1893. An interesting program is in process of arrangement.

CLINICAL LESSONS.

Erythromelalgia: Red Neuralgia of the Extremities—Vasomotor Paralysis of the Extremities—Terminal Neuritis (?).

BY S. WEIR MITCHELL, M.D.,
PHYSICIAN TO THE ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

I THINK myself fortunate in being able to show you this morning the two cases now before us. One is a typical example of vasal spasm in the arterioles of the fingers and is known as Raynaud's disease. The other is the remarkable malady which I first described in 1872, and to which in 1878, at Professor Ashhurst's suggestion, I gave the name of *erythromelalgia* (redness, extremity, pain); "red neuralgia" some like to call it. It is inconceivable that these two disorders should ever have been confused, and yet at least one able observer speaks of erythromelalgia, dead fingers, local asphyxia, local syncope, symmetrical gangrene, as all being simply different types of Raynaud's disease. I hardly imagine anything clinically more strange than to consider the cases before us as one. Examples of Raynaud's malady are not rare; cases of erythromelalgia are very uncommon.

Here before you are two people. One is a pale, nervous, excitable woman, whose condensed history my clinical aid will presently read. We shall somewhat abbreviate, for the whole matter has become familiar, and except as to the mechanism of causation[1] concerning the clinical features, we know all that we are likely soon to know. I show the case now only as a contrasted clinical picture.

C. L., single, thirty years of age, a dressmaker, is an intelligent woman. She has had no grave illness, but after a long strain and much work she began to have the well-known corpse fingers. These attacks became severe and more lasting, and by and by passed at times into the condition of local asphyxia, the fingers becoming livid in tint. Later, she had slight gangrenous loss of all the finger-tips. You see the scars on the finger-tips, now white and cold. This state may go and come, or may end in the livid condition when the returning blood stays in the part and becomes black.

Observe now that when I prick the livid finger the blood flows out black, and does not redden by exposure. It is clear that it is locally charged with excess of carbon dioxid, but has no other peculiarities. Many of Raynaud's cases suffered much pain. This woman, like others I have seen, has had but little.

Turn now to this man in the rolling chair. Thin, ruddy, anxious-looking, he is in no wise hysterical, and is both patient and intelligent. His face bears the signal lines of pain. Look at his foot, as it lies on the extended leaf of the chair. There is nothing notable about it, except the scars of the old injury. It is like the other foot—neither red nor pale. He says it aches continuously, a dull, deep-burning ache. Also, as you see, it is tender to deep pressure and less so to lighter pressure, except as to the outside and as to the heel and fourth and fifth toes. I ask him to rise. He does this aided. He positively will not stand on the foot. He leans now on a chair. Almost at once three of the toes become of a bright, rosy tint. Then, beginning in island-like spaces, a deeper tint covers a large part of the foot. The arteries throb. The veins stand out in strong relief. In a few minutes the vascular tumult lessens. The arteries cease to throb. The redness becomes dusky, or in places purplish—not livid, as in the woman's case. At once the dependency of the foot brings increase of pain, and this gets worse until he will not stand longer or falls fainting.

In like degree the hyperæsthesia, both of depth and surface, is augmented. Finally, the touch of a feather gives pain, and deeper pressure sends darts of pain up the track of the posterior tibial nerve. At last the pain is unendurable and I must let him put the foot up again on a chair.

It is interesting to observe how unstable everywhere is his surface circulation; how flushes come and go over the legs and trunk, and how notably the other foot changes color.

Surely, no two more entirely separate groups of symptoms could be found: this cold, white hand, with its pale fingers, free from pain of any moment and more or less anæsthetic, and now presently livid; this hot, deep-red foot, so painful that its torment brings out the sweat on the sufferer's brow.

Before dismissing these cases I desire to say a few words as to the contrasts they offer.

Lannois, whose book I mentioned, thus characterizes local asphyxia, or symmetrical gangrene and erythromelalgia. I have somewhat altered his definitions:

Local asphyxia (Raynaud).	*Erythromelalgia* (Weir Mitchell).
Sex: Four-fifths females.	In twenty-seven cases two were women.
Begins with ischemia.	Little or no difference of color is seen until the foot hangs down in upright posture, when it becomes rose-red.
The affected parts become bloodless and white. In certain cases there is the deep, dusky congestion of a cyanosed part, with or without gangrene.	The arteries throb, and the color becomes dusky-red or violaceous in tint.
Pain may be absent or acute, and comes and goes; has no relation to position. May precede local asphyxia.	Pain always present; worse when the part hangs down or is pressed upon. In bad cases, more or less at all times.

[1] Med. Record, N. Y., July, 1885.

Unaffected by seasons. In many cases all the symptoms can be brought on by cold.	Worse in summer and from heat. Eased by cold.
Anæsthesia to touch.	Sensation of all kinds preserved.
Analgesia.	Hyperalgesia.
Temperature much lowered and unaltered by posture.	Temperature greatly above normal. Dependency causes in some cases increase of heat; in others, lowering of temperature.
Gangrene local and limited; likely to be symmetrical.	No gangrene; asymmetrical.

Erythromelalgia, then, is a chronic disease in which a part or parts—usually one or more extremities—suffer with pain, flushing, and local fever, made far worse if the parts hang down. There are mild cases which do not progress, and which may come and go. There are others which exhibit all the symptoms to such a degree as to make the disease one of terrible torment.

In 1878, when my second paper was published, I predicted that the malady would soon be shown to be more common than it appeared then to be—and this has proved to be the case. Lannois' treatise [1] gives many cases, and of late the German observers have delineated it with their usual care, and especially Gerhardt. At the time I wrote, I would, if driven to be positive in statement, have inclined toward considering this malady as due to some form of spinal disorder. And this may yet prove more or less true of some of the cases, or of some stage of the cases. But at present the reasonable explanations incline rather toward some form of that new clinical perplexity, peripheral neuritis. Light is cast on the matter by the later history I have just obtained of the case of Mr. K., whom I saw in 1876, and whose story it seems worth while to give here at length, before returning to the discussion of causes. Here is a brief *résumé* from my paper of 1878.

CASE II.—G. K., single, clerk, lost his right arm in war, 1862. Army life was too much for his strength, and in 1864 an attack of typhoid left him with impaired vision—relieved in 1872 by glasses. Between these latter dates the foot-trouble began, with burning pain and redness, made much worse by exercise. He persisted in walking until he caused blisters, and these were the only nutrition-changes I have ever seen in this disease. In 1875, with some evidences of paresis in leg and arm, the remaining hand became red, tender, and painful. The case was typical. In July, 1877, after extremities of anguish, Mr. R. went to Elmira, where Dr. Morris Lewis saw him for me and made notes. There was little change as to the disease. But he had become silent and morose, and was unable to be out of bed. From November to July of 1877 he had nine attacks of convulsions or rather of general rigidity. He spoke slowly and in whispers. Clearly he had become more or less hysterical.

There was slight œdema from the waist down. Pressure on the spine caused pain, and the extremities were very tender everywhere. The finger-ends were bluish and cold. The last two phalanges were smooth, red, and shiny—reminding one of certain cases of traumatic neuritis. There was great pain in the feet, the worse for heat and dependency. Also, he complained of girdle-pain at the waist. Sensation in all forms was normal as to motion; a fine tremor existed throughout upon effort. There was very quick exhaustion, but no other distinct loss of power. Temperature and electric tests were difficult and objected to. Faradic reaction in the arm-muscles was normal. The same current in the leg-muscles caused no motion; a stronger current caused general convulsive movement of the limb. There was no other obvious change.[1]

To my surprise, I learned of late that this unfortunate gentleman was still alive. One of our staff, Dr. Burr, has visited him at my desire, and this is the present history, after at least twenty-three years of varied suffering.

DR. BURR'S REPORT.

"The patient's condition remained the same from the time Dr. Mitchell last saw him until 1883, during which year the redness in the feet slowly disappeared and the pain grew less severe and finally became a mere ache. There has never since been a return of the color. For some years the legs and abdomen have felt numb or, as he expresses it, he is 'dead from the belly down.' He has never had a bedsore. He has lost flesh during the last part of five years, but at times increases a little in weight. He lies on the right side or back, with the eyes covered by two bandages. Lying on the left side causes pain in the left shoulder. The room is kept darkened. He has not read for many years, not because vision is bad, but because doing so causes occipital ache and nervous feelings in the head. The voice is whispering, and so low that he is heard with difficulty. There is remarkable emaciation, the abdominal wall almost falling against the spine. The skin is very pale, but the mucous membranes are of fairly good color.

"As he lies in bed the feet fall forward in lax extension. He can flex and extend the toes, ankles, and knees, and adduct and abduct the thighs while the legs are supported by the mattress, but he cannot raise the legs from the bed. He can move the left arm weakly in all directions, but has not strength enough to grasp anything. He cannot feed himself. There is no more wasting of the legs than of the rest of the body. Position does not now influence the color of the extremities. There is no œdema of the feet. The skin-temperature is good to the touch. There is no rigidity at the ankle-joint, knee-joint, or thigh-joint, passive motion being perfectly free. No trophic joint-lesion is present. As to sensation, he localizes touch in the legs and the arm perfectly. Contact is often felt as pain, more so in the legs than in the arm. There is no more pain on pressure over a nerve than over a muscle. There is no discoverable swelling of the nerve-trunks.

"The reflexes in the legs are all increased. A slight touch on the soles, and at times, indeed, on any part of the legs, will cause the member to be quickly and forcibly drawn up, and sometimes the movement may extend to the other leg. The knee-jerk is quick, large, and spastic. Clonus is present in both feet, and at times, patellar clonus can be produced. The left elbow-jerk is present, but not very marked. The muscle-jerks are capricious. Chin-jerk cannot be obtained.

"The bowels are moved once in eight or ten days, always by strong purgative medicine or mechanically. He never has a voluntary stool. He cannot hold water

[1] Erythromelalgia, p. 71. 1880.

[1] Amer. Journ. Med. Sci., July, 1878, for full report.

after the desire to micturate comes on, but the stream is good and there is never dribbling. Sexual desire and power are abolished. Examination of the abdominal and thoracic organs is negative. Sleep is variable and often restless. Violent jerking of the legs is frequent during slumber. He now has no violent pain in the feet, but at times much severe aching. He can foretell a storm by increase in foot-pain and shoulder-ache. He complains much of queer, indescribable feelings in the head.

"There is no difficulty in swallowing. Appetite is variable. Mental condition is good, but all mental effort is disliked. I believe that at the present time an hysterical element is added to his organic disease. His manner, voice, and head-symptoms point in this direction."

On the 13th day of April, 1893, this patient died in Washington, and to my regret no cadaveric section was allowed.

Seen in the wisdom-yielding light of many years this case seems to have been originally a neuritis of peculiar type, resulting, as time went on, in the addition of hysteria and of lasting spinal lesions to be discerned in the clear language of spastic conditions, excitable reflexes, clonus, and girdle-pains. Neither hysteria nor the added spinal malady may be essential features of the disease. I have seen them in other cases, not always with the same manifestations as here. And on the other hand, I know of erythromelalgias of milder type, which, after twenty-five years, have altered little, and certainly have not become worse or added a single spinal symptom. The old age of a case may really be of more analytic value than a cadaveric section. In K. the neuritis clearly ceased to be a very active agency. The sequent spinal malady, probably at one time itself a central and limited neuritis, remains and, too, the hysteria is visible enough. And now let us turn anew to the present case. Mr. K.'s case, as I read it to-day, might have been better studied in 1876. I did not realize its importance. I lay before you Dr. Rhein's notes of the present case, taken in my ward. Dr. Burr has also given it his careful attention. It is so pure a type of erythromelalgia that I consider it most desirable to study it with extreme minuteness.

T. S., twenty-one years of age, a stonecutter, applied for treatment at Dr. Goodman's clinic in February, 1893, on account of pain in the right foot and difficulty in moving it. Dr. Goodman, promptly recognizing the neurotic element in the case, kindly transferred the patient to the care of Dr. Weir Mitchell. The family and personal history is negative.

In February, 1892, the patient, with several other men, was raising a stone weighing between ten and eleven hundredweight, when the board supporting it broke and one end of the stone fell three feet and struck the patient's right foot just in front of the ankle-joint. In a few moments the stone was removed. The patient was unconscious for a little while. After about an hour he again became unconscious, probably because of the great pain, and remained so for four hours. The wound was superficial and bled very little. The foot and leg, half-way to the knee, swelled considerably. The patient was kept at rest for four days and hot water was applied to the leg. Six weeks later a large swelling upon the sole was incised for relief of a supposed abscess. Little bleeding followed, and there was no evidence of suppuration. Ever since the injury there has been difficulty as to motion in the ankle, owing to pain. He began to walk December 24, 1892. The swelling did not disappear entirely until two months after the accident. Walking caused sharp pain under the internal malleolus and just in front of the ankle-joint. In damp weather there was pain in the right great toe. The right foot felt warmer to the patient than the left. The effort to walk was soon given up and the horizontal position permanently assumed as the only one possible to be borne.

There are at present five scars due to the injury on the dorsal aspect of the foot. One, 1 cm. by 1.4 cm. in size, is situated 6 cm. internal to the median line of the foot and 9 cm. below a line connecting the malleoli. The second, about the same size, is 7 cm. to the inner side of the first. In the median line and anterior to the first are three smaller scars each about 2 cm. in diameter. They are all dark purplish and hypersensitive to pressure. He is unable to stand up or, rather, to sustain any part of his weight on the right foot, except for a moment, by resting on the heel alone.

The whole of the right foot, as he lies at rest supine, the leg being extended, is slightly redder in places than the left, but after a few minutes in this horizontal position it is observed that, save for the tint of the scars, the feet are indistinguishable in hue. When standing erect, with the right foot hanging down, the foot becomes flushed at once; the first and second toes take on a rare red, and this extends, appearing here and there in islets of deepening color until the whole foot is of a dark, dusky tint, which becomes more pronounced the longer he is up. The upper limit of redness is marked by a dark-red band on the ankle, 1⅜ inches above the lower border of the internal malleolus. It encircles the limb, except for an irregular space, on the outer aspect.

The beginning of the flush in the pendent foot is marked by increase in the size of the veins and in a visible and rapidly augmented force of arterial pulsations. It is a true vascular storm. After a few minutes the veins remain large, but the arterial throb lessens; the color becomes more and more purplish, but even after a half-hour, when the patient stood on crutches, was never of the smoky tint seen in local asphyxia. When again put at rest and supine, all of the vascular symptoms disappeared quite promptly. The whole foot is over-sensitive in all positions. The hyperæsthetic areas differ, according as the part is level or pendent. It is hypersensitive to pain and to heat and to cold and to pressure. The diagrams make clear the facts without need of fuller verbal statement.

When lying on a level slight touches give no pain, but the least increase of pressure hurts. Pin-pricks cause extreme pain; all degrees of heat or warmth are over-appreciated up to the knee. The same degree of heat and also of cold seem, as the case might be, hotter or colder than they appear to be when applied to the other leg. This is also far more notable when the tests are made in the flushed areas.

There is constant ache of the right foot, even when at rest on a level. Motion, passive or active, makes it unendurable. If upright, it grows far worse, and he at last becomes faint. When erect, the least touch is productive of extreme pain.

The outer side of the foot, supplied by the external saphena, is unaffected, and this is true of the heel, which is supplied by the plantar cutaneous branches of the posterior tibial nerve. The rest of the plantar surface, supplied by the internal and external plantar nerves; the inner surface and dorsum of the foot, supplied by the internal branch of the musculo-cutaneous nerve and the long or internal saphenous nerve; the adjoining sides of the great and second toes, supplied by branches from the anterior tibial, which communicate with the internal branch of the musculo-cutaneous nerve, are involved. The area of beginning sensitiveness up the posterior leg and thigh is supplied by the small sciatic. The light shading shows the areas sensitive to light pressure, while the dark shading shows the areas sensitive to firm pressure.

Fig. 1.

Motion. The power over extension and flexion of the foot is hard to study because the pain inhibits motion. At rest there seems to be power to move the ankle and toes. Above the knee the movements appear to be with normal power.

Dynamometer: Hand, right, 158; left, 155.

There is marked atrophy of the calf-muscles, chiefly involving the anterior group. The circumference of the right calf 5 cm. below the tubercle of the tibia is 27.6 cm.; of the left calf, 30.7 cm. There is also some wasting of the vastus externus and vastus internus, the circumference of the right thigh a few inches above the knee being 39.5 cm., while that of the left thigh is 42 cm.

The circumference of the thigh at the highest point is, on the right, 51 cm., on the left side, 50 cm.

There is, when at rest, a fine rhythmical tremor involving the whole leg, and when circular pressure is made about the calf muscles it is increased. When the leg is long elevated above the level of the pelvis this tremor gradually disappears. Besides this there may be observed, occasionally, a clonic spasm of the flexors of the first, second and third toes, much increased as to number and force when the foot hangs down. There is also seen a fibrillary tremor of the calf-muscles, more especially posteriorly and of the posterior thigh-muscles.

The foot was occasionally re-examined when pendent. The pain varied, as did also the color. The patient says it is always worse in bad weather. Finally, the foot was elevated on an inclined plane, 40°, for three weeks. This rather lessened the pain, but made the whole posterior tibial nerve very tender. After a day or two of rest at a level this passed away; nor has there been at other times sensitiveness on pressure of any nerve-trunk outside of the area of flushing.

When, at the end of the three weeks, the foot was permitted to hang down, all of the symptoms at once returned in their utmost severity.

A day later, a bandage restricting the return of venous blood was put on at various levels to see if this would cause the vascular storm seen in the pendent foot. It did not. The right foot scarcely flushed more than, under like circumstances, does the normal member.

Reflexes: Right knee-jerk, + +. Spastic; reinforcible by M. and S.

Left knee-jerk, normal.

Ankle-clonus, right, six or eight beats.

Ankle-jerk, right, + +. Spastic.

Ankle-jerk, left, normal; no clonus.

The arm-reflexes are normal.

Muscle-jerks: To blow, right, below knee, excessive as compared with left.

All skin-reflexes are normal.

Electric examination (made by Dr. Willits).

Far.: Foot-extensors, ½ in. coil, right leg; 1 in. coil, left leg. Foot-flexors, ¾ in. coil, right leg; 1 in. coil, left leg.

Extensors (tibialis ant.): Galv., k. cl. c., 4 milliampères, right leg; k. cl. c., 5 milliampères, left leg. Flexors: An. cl. c., 5 milliampères, right leg; an. cl. c., 8 milliampères, left leg.

There is, therefore, quantitative increase in the leg-muscles of the affected side; no qualitative change. Sensation to rapid faradic current is lessened on the affected side.

The eyes were examined by Dr. de Schweinitz, who found vision, pupils, fundus, form, and color fields, all normal. The heart has a faint systolic murmur at the apex. The lungs are normal.

Examination of the surface-temperature of the legs gave the following results: Mouth, 98.6° F. Legs flat in bed—the thermometer on dorsum of foot, behind great and second toe—right foot, 95°; left foot, 87.8°. Legs hanging over side of bed, after thirty minutes, right foot, 95°; left foot, 86.6°.

Mouth, 101.8° (patient has slight pharyngitis). The patient being flat in bed: right foot, 96.8°; left foot, 94.6°. Legs hanging: right foot, 95.8°; left foot, 92.6°.

Repeated examinations were made. There were marked variations of temperature in both extremities. Once both feet were colder than the thermometers would register, viz., 86° F. The affected foot was always the warmer. The temperature fell when the feet were pendent.

No record of treatment is here added, as nothing did good. The man was wonderfully patient, but wore a look of suffering and was absolutely free from hysteria.

This story, as told in Dr. Rhein's notes, but too well

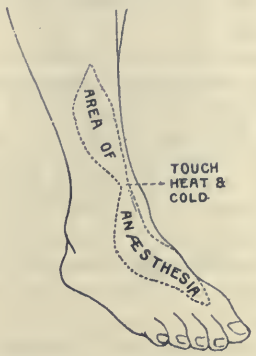
illustrates the obstinacy of grave cases of erythromelalgia, and accords with a long and miserable accumulation of therapeutic failures. I never saw a bad case get well. A few milder examples have varied much, or even seemed to become well, or remained slight enough to be borne. I know of one case, that of a woman in middle age, in which the pain and flush, limited to the dorsum of the foot, comes and goes, seemingly without cause. Nothing helps her, but rest in bed is unavoidable. The usual treatments have failed in this present case, and I have no desire to repeat what has proved valueless.

Whatever may have been the originative cause in other cases, here there is a clear story of wound, of the peculiar swelling so common after neural injury, and which has over and over been laid open as an abscess by men not easily deceived. Then there is the gradual increase of tenderness far in excess of that seen in ordinary inflammation. I am of opinion that we have to deal with a general neuritis of the foot caused by the wound.

I shall later return to this question of neuritis, and the quality of it also. We are now concerned with treatment. I have confessed to complete therapeutic defeat in all my previous cases. It has seemed to me that it would in this man's case be reasonable to cut the nerves which are as to motion unimportant, and to do this near to the foot, and as to the two great plantar trunks, to stretch these—I shall ask Prof. Keen therefore to exsect portions of the internal saphenous and musculo-cutaneous nerves and to stretch, as I have said, the two plantars. These measures ought to largely destroy feeling on the dorsum and the inside of the sole and dorsum, and by the stretching of the terminal branches of the posterior tibial much lessen the sensibility on the sole. The anterior tibial, if one may trust the *Anatomies*, has a small share in the innervation of the foot, but the inosculations and interchange of nerve-fibers are such that I may find, as one does in the hand, that a section by no means strengthens one's esteem for the pictures and statements of the anatomist. The step I propose has not been taken before in this disorder, but is a common enough resort in truncal neuritis. My hope is that the operations I contemplate will lessen the reflex influences which cause the vascular congestion and will so diminish sensibility as to permit massage to be painlessly employed.

Dr. Keen operated on April 10th. He exsected two and one-half inches of the musculo-cutaneous nerve, and the same length of two branches of the internal saphenous. The two end branches (plantar) of the posterior tibial nerve were stretched at the internal malleolus with a traction of fifteen pounds thrice used. The result next day was remarkable. There was almost immediate relief. The foot could be squeezed, pinched, or pricked without pain. Anæsthesia, as shown by the accompanying diagram, was not as extensive as we were led to expect it might be. The day following operation the temperature of the feet was: R., 95° F.; L., 93.5° F.; mouth, 99.5°. On the right, clonus was still present and the knee-jerk was still excessive. The wounds healed in a few days. On the 4th of May the patient began to walk on crutches. Clonus had then disappeared and the reflexes were no longer exaggerated. There was still some flushing of the foot when pendent, but no pain or hyperæsthesia. When discharged, May 6th, he could walk well, but was ordered to continue to use crutches as a measure of precaution, and had also a bandage applied daily. Dr. Kyle reports cultures from blood and nerves obtained at the operation as yielding purely negative results.[1]

Fig. 2.



On May 12th, S. reappeared at my clinic. He was able to walk a little, but refrained, at my request, from much use of the legs. The flush is lessened; the arteries do not throb. He stands and moves without pain. Above all the temperature of the pendent diseased foot is now less than that of the left member.

June 7th, S. is reported well and walking easily without crutches.

The tendency of recent writers seems to be, as I have said, toward considering erythromelalgia as a neuritis. But suppose we accept this view, and in the light of the two cases I have given it seems more than probable, it by no means sets the matter utterly at rest. Neuritis is becoming a sad puzzle. We may have it with paresis and little pain; we may have it without notable paresis and with horrible pain. It exists with or without myositis. Again, it may give rise to causalgia, joint-troubles, and alterations of nails and hair. It may fail to disturb nutrition or greatly to alter local heat; and lastly, if erythromelalgia be a neuritis, it may cause pain and flushing, and to these, increased enormously by dependency of the part, may add a rise of temperature which few local fevers show in acute inflammation.

You see that to give a name to a possible cause does not always help us. If each of these groups of symptoms be due to neuritis, why do they so vary? We may conclude that the nerves are subject, like the spine, to inflammations affecting only certain systems, but in the nerves the fibers of sense in their kinds, of motion and nutrition and vasal control are, as we think, scattered through the parent nerve, whence it seems hard to comprehend the possibility of isolated inflammation of systems. And yet to this we seem driven. The difference in effect between neuritis of a trunk, of the minuter nerves, or of the terminal plates has not as yet been fully considered. Certainly the constant, general, deep, and surface tenderness of erythromelalgia looks to me much like a condition of diffused, what I might call *terminal*, neuritis,

[1] The pieces of exsected nerve were hardened in Mueller's fluid for some weeks, imbedded in celloidin, and stained with carmine. On microscopic examination the musculo-cutaneous and two branches of the internal saphenous were found to be absolutely normal.

sure, like all nerve-end maladies or influences, to cause remote reflex effects. The exsected nerves taken at a part of the nerve-trunk within the flushed area show no signs of inflammation. We may therefore conclude that erythromelalgia is not, as some have thought, a truncal neuritis, but this very negative fact, taken with the symptoms, makes more probable the explanation of a nerve-end neuritis.

Let us return to look at the phenomena which follow letting the foot hang down. The man is seated. He remarks that to make the foot very red he must stand. At once as he rises the tint gets a brighter rose, and goes on as before described. This is really a vascular storm, and soon the throbbing vessels are less violent, and the temperature falls a little or is stationary. In most of these cases pendency causes first a rise and then later a fall of the mercurial column. In this man, as in some others, there is a fall, but less notable on the diseased side.

I think this may vary with the age of the disease. What we see is more than a mere vasomotor palsy. If it were only that, we could with ease flush the foot when, the leg being horizontal, we tie a ligature below the knee. You have seen how very slightly then the foot flushes. The upright posture and the long column of blood seem needed to get a great effect.

In this present case the muscles are, as to motion, over-responsive to electricity, and, as to sensation, but slightly responsive to the same agency. This is unusual. Indeed, to see excess of response in disease is very rare. Also, there is some wasting in these over-irritable muscles, and this adds to my surprise at their too ready reply to the battery in both forms.

Moderate ankle-clonus is present and right knee-jerk in great excess as a spastic reflex. Altogether the grouping of symptoms is uncommon.

The complex symptom-group here considered is not easy to interpret, especially in the entire absence of hysteria. Ordinarily—*apart from the erythromelalgia*—the signals in our present case would usually point to a spinal local and not extensive lesion, and remembering some other histories of erythromelalgia, we are not unprepared for this conclusion. Even then the riddle is but half read. Spastic states of spinal birth do not yield excessive electro-muscular excitations, or swiftly fail us after nerve-stretching and sections.

It is to be remembered that only the older cases present these quasi-spinal symptoms in grave forms. Allan Sturges' case had wasting, with only quantitative reduction of electric excitability. Whether clonus and spastic knee-jerk are ever only of peripheral neuritic origin we do not know. When I froze my own ulnar nerves, repeating Waller's experiments, the related nerves and muscles acquired for a time a wild excess of excitability to all mechanical impressions. It is really an open question.

The typical form, then, of erythromelalgia is probably a painful nerve-end neuritis with or without coexistent inflammation of the parent stems. Probably, too, although the skin may be of normal tint when the limb is at rest, the deeper tissues are always too full of blood, and the temperature supra-normal. Dependency only exaggerates these conditions, except that as to temperature it does not always do so. The abrupt lessening and final loss of pain, local fever, hyperæsthesia, and flushing under the influence of nerve-section and stretching, make it seem likely that much of these symptoms is reflex from inflamed nerve-ends. When they can no longer play mischievously on the centers they are released from certain of the morbid conditions which stand in the way of recovery. I have over and over tried to bring about the same results by hypodermatic use of opium. I have no record of success, but I see that a recent case is said to have been thus helped.

Perhaps some of you may have noticed that when the feet are pendent the temperature in the sound foot falls. This result a little surprised me. I do find mention of it elsewhere, and we shall at once study it with care; as a fact in thermal physiology it may be of interest.

In conclusion, I desire to add that I have seen cases of red neuralgia in which the disorder occurred at any part of the surface in isolated skin-spaces. I suspect, too, that in another species there are end-inflamed nerves in some of the viscera and in the muscles. I hope in future to report a small group of such cases.

VAGINAL HYSTERECTOMY FOR MALIGNANT DISEASE OF THE UTERUS, WITH A TABULATED REPORT OF CASES.[1]

BY RUFUS B. HALL, M.D.,
OF CINCINNATI, OHIO;
FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

THE subject of vaginal hysterectomy for malignant disease is one that has excited much discussion. Those who condemn the operation have been numerous and emphatic in their denunciation of it, while those who indorse it have been as emphatic and positive in favoring the operation as their opponents have been in condemning it. But at the present time the warring factions are practically united as to the utility of the operation, and the advisability of hysterectomy for carcinoma is no longer questioned. With a mortality not exceeding 8 per cent., there is no need, it seems to me, of any discussion as to whether total extirpation is applicable to every case when carcinoma has been diagnosticated early. It is the operation of election when we are certain of our diagnosis. But the question of early diagnosis is the point to be emphasized, because upon it so much depends. It is this that has induced me to bring this subject before you at this time.

From October 31, 1891, to May 16, 1893, a period of less than nineteen months, I have performed eight vaginal hysterectomies.[2] During that same period I have had referred to me for operation twenty-eight cases of carcinoma of the uterus, in which the disease had advanced so far that I refused to operate, the broad ligaments or other organs being involved. I do not mean that total extirpation could not have

[1] Read before the American Association of Obstetricians and Gynecologists, June, 1893.

[2] Seven for carcinoma and one for complete prolapsus.

been performed, but the disease was not confined to the uterus, and would therefore return; or, we might more correctly say, would continue. My experience in this particular quite agrees with that of other operators with whom I have conferred upon this point. If we are to hope for good ultimate results from total extirpation of the carcinomatous uterus, the operation must be performed early, before the disease has advanced to any great extent. Therefore it is of the utmost importance to our patients that we make a diagnosis of the disease early. It has occurred to me time and again, that if there could be some means devised by which the patients during this period could be seen earlier by the family physician than is now the case, many valuable lives might be saved.

But how is this to be accomplished? In the same manner that the early operation for the removal of ovarian tumor was popularized. By educating the laity, by the diffusion of knowledge upon this point upon every possible occasion, it will only be a question of time when the good work will be crowned with success. To do this will require a patient and persistent effort on the part of the family physician, as it must be conceded by all that he will see the vast majority of these cases before they visit the specialist. He must educate the public mind up to the point of realizing the necessity of early diagnosis and operation, if all the benefits to be derived from surgical science are to be obtained. I am not here to find fault with or to censure the members of the profession, but to contribute my mite, if possible, to the great volume of medical knowledge for the benefit of humanity. With this object in view we should all lay aside prejudice and many of our old ideas regarding the early diagnosis of carcinoma of the uterus, and study it from the clinical data at hand. By doing this we shall be able to master many of the difficulties of early diagnosis that have heretofore surrounded the subject.

The fact that the family physician sees a case of malignant disease of the uterus in his own practice very infrequently is inclined to make him timid and uncertain in many cases as to the correctness of his diagnosis until he has watched the progress of disease for many weeks, and in some instances many months, when, alas, he realizes the fact that it is all too true that his first suspicions as to the nature of the disease were correct, and his patient is a subject of carcinoma of the uterus; but the disease has then advanced so far that relief is impossible. You may say that this statement is too broad; yet I assure you that it is only a fair one of facts as I have found them to exist in the past, and as I believe them to be at the present time. On the other hand, I not infrequently receive a letter from the attending physician at the time of the patient's first visit, in which he says that he was first consulted by the patient in reference to her present illness a day or two before her visit to me, yet the disease has advanced too far for any radical operation to be made. But the fault here is with the patient. The widespread belief in the community that women at or near the menopause are accustomed to unusual discharges, aches, and pains, and they must not pay any attention to these, as they will disappear when the change comes, is not at all true, but a *false* doctrine, beset with many dangers to women nearing the menopause. This false doctrine was the cause of the delay in many of the late cases just referred to.

Again, not a few women in the country districts will object to the proposed examination by their physician for months, possibly until the disease has invaded other structures than the uterus, and they only consent to a vaginal examination when they become alarmed by the frequent hemorrhages, at which time the disease may have advanced so far as to render the case hopeless. This can only be remedied by the determined effort of the family physician, urging upon his patients between forty and fifty years of age the stern necessity of looking at once after what may appear to the patient as a most trifling discharge from the vagina. It would only require a few years' time to educate the laity up to the point of realizing the necessity of early attention to these symptoms, as they now recognize the necessity of early operation for the removal of ovarian tumors. When women once understand the benefit to be derived from an early diagnosis and proper treatment in these cases, and contrast this with that of delay and death, they will present themselves to their family physician for examination earlier in the disease than they do at the present time.

The clinical histories of all cases coming under my observation for the first few months of the disease do not differ one from the other in a very marked degree. It is to this that I wish to direct especial attention, more particularly as we not infrequently hear the family physician say: "Why, doctor, this cannot be carcinoma, for there is lacking that horrible stench which I have been taught to believe is invariably present in all cases of cancer of the uterus." "Yes," I answer, "she will have it at no distant day, and when that comes the disease, as a rule, will have advanced so far that total extirpation will be out of the question, or at least a questionable operation." What we want is to be able to make a diagnosis before the disease has advanced to this point. It therefore behooves us to look carefully after the clinical history of all women at or near the menopause, who have in their past life enjoyed reasonable health, but who suddenly commence to complain of any symptoms of uterine disease.

. In every instance except two in the thirty-four carefully recorded cases comprising the basis of these remarks, the first symptom to attract the attention of the patient was a slight watery discharge from the vagina, and, at or about the same time, a sense of weight or fulness in the pelvis, and slight discomfort in the back. This slight watery discharge continues at irregular intervals, is sometimes more marked than at others, and it is several weeks, and in quite a large number several months, before other symptoms develop, attracting the patient's attention. If these cases were carefully examined at this stage of the disease there would be no difficulty in detecting malignant disease if it existed. When the disease has advanced still further, the most prominent and constant symptom consists in irregular discharges of blood from the vagina between the menstrual periods. At about this time the patient first observes that the watery discharges commence to irritate her person, and at times to have a slightly disagreeable odor. She now often complains of vague pain in the pelvis. Two of my patients said that the first symptom that they could associate with their disease was sharp shooting pain in the pelvis. In both of these cases the disease was far advanced when they came under observation. Within three or four months after the first symptoms were observed, 50 per cent. of all the cases developed some irritability of the bladder. I am aware of the fact that we may, and frequently do have all of these symptoms in women who do not have carcinoma. It is for this very reason that there is so much danger of overlooking the true cause of these symptoms while the patient is the subject of commencing malignant disease. But these symptoms, occurring at or near the menopause, in a woman who has always enjoyed excellent, or even good health, so far as her sexual organs are concerned, should not only suggest to the attending physician, but should demand at his hands an early, thorough, and complete physical examination, to determine whether or not the patient is the subject of malignant disease. The physician should be unusually cautious and anxious to make a correct diagnosis early, when so much depends upon it. If this course were pursued in every case, we should be able to see a much larger number of cases before the disease had advanced so far that nothing can be done to save them. The following eight are all of the cases of vaginal hysterectomy that I have performed since October 31, 1891, and are tabulated in the order of their occurrence. They all recovered, and are all living at this time; yet the three-year limit, the period at which it is conceded that they are exempt from recurrence, has not elapsed in any of the cases, and therefore it is too early to predict as to ultimate results.

THE INFLUENCE OF THE SEXUAL ORGANS UPON REFLEX OCULAR NEUROSES.[1]

BY HOWARD McI. MORTON, M.S., M.D.,
OF MINNEAPOLIS, MINN.,
PROFESSOR OF CLINICAL OPHTHALMOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, OPHTHALMOLOGIST TO THE ASBURY METHODIST HOSPITAL, AND CHIEF OF THE ASBURY METHODIST HOSPITAL DISPENSARY.

IN this decade of pin-point concentration upon particular divisions of the wide field of medicine, and in a period in which we bend all our energy to

[1] Read before the Minnesota State Medical Society, May 22, 1893.

the study and observation of the morbid changes within an organ, or set of organs, we are too frequently guilty of charging the causes of various remote disturbances to these organs, and are frequently too ready to assert that in the organ in which morbid manifestations are found may reside the causes.

I believe that this statement is amply and abundantly verified in the special field of ophthalmology. In almost any issue of our current medical journals one may find reports of cases in which many diverse, interesting, and remote phenomena are, with great truth, traced to the eye as a cause. The "Record Book" of any ophthalmic surgeon contains the records of many such cases. The habitual finding of such associations, to the exclusion of other affections of the body, is dangerously conducive to a careless and superficial process of reasoning.

To demonstrate that the eye may be and is affected by peripheral and remote foci of irritation, through the medium of the "reflex nervous system," I shall present a few cases illustrating the close relationship that may exist between the sexual organs and the eye.

Case I.—Mr. H. A. M , twenty-two years of age, white, stated that, ever since he could remember, his eyes had caused him pain and annoyance. He had been unable to hold his eyes widely open on account of the dread of light and the profuse lachrymation that followed such an effort; he has worn glasses that partially corrected a hyperopia of high degree, and with these he was able to read but one or two minutes without inducing such severe pain that he had to cease. He complained especially of smarting and burning deep in the globes. The ophthalmoscope revealed in both eyes marked hyperemia of the optic discs, and a "water-silk" retina. In the left eye were noted a few patches of disseminated choroiditis, indicative of long-standing eye-strain and irritation. He did not use tobacco, but was addicted to moderate indulgence in alcohol. This young man was operated upon by Dr. J. H. Dunn about December 20, 1892, for paraphimosis, and the symptoms which had troubled him for a lifetime disappeared as if by magic. Within a period of one week he could hold his eyes wide open in bright daylight, and he could read without glasses for from half an hour to an hour without fatigue, whereas before, with glasses that partially corrected his refractive error, he could read but one minute. The lachrymation had disappeared, and the reflected light from the ophthalmoscope did not annoy him. Further, the fundi had been relieved of the signs mentioned. Circumcision gave perfect relief. The connection between cause and effect here is too obvious to escape us. The patient, a lifelong sufferer from asthenopia and retinal hyperesthesia, was immediately relieved by the removal of the irritation situated in the genital organs.

Case II.—I am able to report this case through the kindness of Dr. E. B. Patterson, of Michigamme, Mich. Dr. Patterson says: "A year ago an exceedingly bright, precocious child of five years was brought to me by his physician. The little fellow was affected with diplopia that annoyed him sorely. He had been seen by a number of competent ophthalmologists, and several pairs of glasses had been ordered, but with no benefit. Graduated tenotomy had been advised by some. His physician, a man of rare scientific attainments, had been unable to detect any intrinsic cause for the trouble, and had reached the conclusion that the phenomena were caused by some reflex irritation. After careful examination of the case I fully concurred in his opinion, and search was made for the source of the trouble. It was found that the child would often act as though there was some irritation of the genital organs, and by careful examination it was found that the prepuce was firmly adherent to the corona glandis, and that back of this there was extreme sensitiveness. A separation of the parts was advised, and subsequently made by his physician, who, on freeing the prepuce, found a considerable quantity of decomposed smegma. This was removed, and in two weeks the diplopia had disappeared, and with it much of the nervousness that the child had previously manifested.

The following two cases are reported to illustrate another phase of reflex irritation arising in the genital organs and overflowing to the eye:

Case III.—H. S., eighteen years of age, consulted me in the early part of 1893; he had been a sufferer with his eyes for two years. During this time he had been treated by a number of competent oculists, fitted with glasses, but had derived no benefit. His family history was good; he did not use tobacco or alcohol; he was wearing glasses for the correction of 0.5 D. of astigmatism in each eye. His eyes were exquisitely sensitive to any handling or irritation; and on throwing light into the eye a profuse gush of tears followed. The discs were very hyperemic, the retinal veins more than usually pulsatile, vision blurred, and the eyes tired after reading but a few words. I reduced the strength of his astigmatic glasses, put him on dilute hydrobromic acid and Fowler's solution, and practised his extra-ocular muscles with prismatic exercises. Under this treatment he seemed to improve for a time, but I was baffled by the very changeable condition presented by the eyes; at the time of one visit he was much better; the next—only a few days after—he was intensely irritable. After convincing myself that the cause was not wholly to be found in the eyes, I set about to find the source of irritation. After much questioning I found that he was a masturbator. He acknowledged that after the practice of the habit his eyes were much worse. Admonishing him of the vital necessity of stopping the habit, and administering hyoscin and bromids, the condition of the eyes steadily improved, and to-day they are much better than for several years. In this case the absence of the relapses, which were so conspicuous before, and his subsequent *steady* improvement, left no doubt of the bearing that the practice of his habit had upon the eyes.

CASE IV.—T. J. T., eighteen years of age, was a case very much like the preceding one, although at the start he confessed his failing, and suspected that it influenced the condition of his eyes. After correction of the refractive error, and the promise that he would correct his habits, improvement was as noticeable as in the previous case.

REMARKS.—The theoretic and experimental consideration of the "Reflex Theory," and of reflexes, forms one of the most enticing chapters in medical literature; and the clinical demonstration of them is most valuable, as it explains many otherwise obscure cases. The relationship of the sexual organs to the eye may at first thought seem very distant and problematic, until a clear idea of the possible conditions that may result from some derangement of the myriad number of reflex pathways is obtained.

We may, in many respects, liken this great system of afferent sensory fibers running to the great central depot, the cord and brain, and the out-going efferent fibers ramifying to every organ, to a great railway terminal. Just so long as the myriad sensory impressions are properly switched off on to the return track, all goes well; otherwise we have trouble. A reflex act is a dynamic response to a sensory irritation. This response may assume the form of vasomotor, secretory, or motor acts. The law of reflexes requires a return stimulus to go to or near to the seat of primary irritation; or to manifest itself in some normal trophic or vasomotor change. When this does not occur, pathology has its beginning. Given a normal condition of the reflex centers, we have these impulses returned to the organ whence they came, or manifesting themselves in natural vasomotor or trophic changes; but if we have some cause to intensify and elaborate the different impulses, it is not difficult to conceive that they may be bound off into a path of least resistance, and flow into some innocent organ or set of organs.

In the large majority of cases of eye-strain the impulse is either returned to the eye, and manifests itself in the form of asthenopia, blepharitis, or conjunctivitis, or is stored up in the brain, and manifests itself in one or other of the protean forms of headache. The subtle and molecular factors which influence the paths of propagation of reflexes are so mysterious that no definite laws have yet been advanced that would clinically hold good; although in this relationship of the eye and sexual organs, Pflüger's law might seem correct—that is, "Whenever an afferent cranial nerve evokes reflexes, the impulse travels among centers from before backward; but whenever an efferent spinal nerve has produced reflexes through the center of the cord, the impulses spread from behind forward."

After looking at the course and termination of these cases, we may, I believe, justly come to the following conclusions:

1. That foci of irritation in the genital organs may, through the medium of the reflex nervous system, induce various neuroses of the eye.

2. That while the precise laws that govern the passage of these impulses from other than their natural return channels is not known, it is probable that the impulses, greatly intensified by the condition of the reflex centers, which are connected by commissural bands, flow on to fibers that present a field of less resistance than the usual efferent pathway, and thereby flow into an innocent organ, with dire results.

3. That the full appreciation of this probability should be constantly in the mind of the ophthalmologist and neurologist, and stimulate both to search for all possible peripheral foci of irritation.

4. Lastly, that it frequently happens that the trouble disappears upon the removal of the remote point of irritation.

ON THE DISTRIBUTION OF ARSENIC IN THE BODIES OF ANIMALS POISONED WITH THIS SUBSTANCE.

BY E. H. S. BAILEY, PH.D.,
PROFESSOR OF CHEMISTRY AND TOXICOLOGY IN THE UNIVERSITY OF KANSAS, LAWRENCE, KANSAS.

AFTER all the advances that have been made in the science of toxicology, the experimenter of to-day goes back to the time of Orfila for some of his methods. He studies the action of special poisons on the lower animals, and from this action infers what the action would be upon the human system. To a certain extent, these deductions are correct, but in other cases they are false; for it has come to be a fact well known in science that it is impossible to predict positively what the action of a poison on the human subject will be from its action on a particular animal.

There have been numerous experiments made to find to what extent toleration can be established in the lower animals when arsenic is administered to them with their food. Johnson and Chittenden[1] call attention to the fact that the rate of absorption, especially in the brain and muscular tissue, is influenced by the form in which the poison is administered; that is, whether it be in the form of a soluble arsenite or in the form of a partially soluble substance like ordinary white arsenic (As_2O_3). It may be noticed, in passing, that Chittenden, who has made a special study of the subject, and who has had special opportunities to ascertain the amount of arsenic in different por-

[1] American Chemical Journal, vol. ii, p. 332.

tions of the body of the human subject, believes that in case the poison is taken in a soluble form, much more will be found in the brain than when it is taken into the system as white arsenic.

The experiments mentioned later were made in connection with the examination of parts of the body of a man supposed to have been poisoned by arsenic administered in small doses, extending over a considerable length of time. In this particular case I found in the stomach and contents only a trace of arsenic; in the liver 0.68 grains of As_2O_3; in the duodenum and a part of the jejunum a distinct mirror of metallic arsenic, and in the brain, heart, and kidney, a mirror of the metal that could be verified by other tests to prove its identity, although the amount was too small to weigh accurately.

The method used in making the tests, both on the human subjects and on the dogs, was the modification of Gautier's process, as proposed by Chittenden and Donaldson, and described in the *American Chemical Journal*, vol. ii, p. 235.

In experiment No. 1, a dog, weighing about forty-five pounds, and in good health, was fed upon the poison mixed with his ordinary food. He was furnished with an abundance of clean water. The arsenious oxid was dissolved in a solution of sodium carbonate, so that it was in reality sodium arsenite. The amounts given were as follows:

Jan. 10	0.1 gr.	Jan. 15, P.M.	0.2 gr.
Jan. 11	0.1 "	Jan. 16, A.M.	0.5 "
Jan. 12	0.2 "	Jan. 16, P.M.	0.5 "
Jan. 13	0.2 "	Jan. 17, A.M.	1.0 "
Jan. 14	0.3 "	Jan. 17, P.M.	1.0 "
Jan. 15, A.M.	0.4 "		

Total arsenic given, 4.5 grains. A part of the last dose was rejected, but some was eaten the next morning. This was the first time that the animal appeared to be affected by the poison. Six hours after the last dose was swallowed the dog was chloroformed. The analysis of some of the parts gave the following results:

187 grams of liver contained	0.018 grs.	As_2O_3;
which calculated for the whole organ (447 grs.) is	0.045 "	"
The entire heart contained	0.001 "	"
One kidney contained	0.002 "	"

4½ ounces of blood contained a distinct trace, but less than 0.001 grain; 60 grams of muscle contained a slight trace only.

It seems that in this case tolerance was established up to about one grain. Much less than this at the beginning of the series of doses would, no doubt, have produced very distinct symptoms. The experiments were continued over eight days, and yet the amount found in the organs analyzed was small. This is especially noticeable in the liver, where less than one-twelfth of a grain was found, although a grain had been administered thirty hours previously to death, and several tenths of a grain at a later period. How rapidly then must have been the elimination from the system.

The second series of experiments was carried out by two students, under my direction, to ascertain the limit of tolerance with the use of arsenious oxid A dog of about the same size as the first was fed on raw meat, which had been rubbed with powdered arsenic. The following amounts were administered:

1st day	0.2 gr.	8th day	1.00 gr.
2d "	0.3 "	9th "	1.1 "
3d "	0.4 "	10th "	1.3 "
4th "	0.4 "	11th "	1.7 "
5th "	0.5 "	12th "	2.5 "
6th "	0.6 "	13th "	3.5 "
7th "	0.7 "	14th "	5.00 "

After the last dose the dog appeared to be sickened, and four hours afterward he was chloroformed and parts of the body were removed for analysis. During the two weeks the dog had been fed 19.2 grains of arsenic, without any apparent injury to his health; in fact, his coat was more glossy, his eyes more brilliant, and his spirits better than when the course of the experiments was begun.

There was obtained from one-third of the stomach and contents one grain of arsenic, giving three grains for the whole organ. One-fifth of the liver contained one-eighth of a grain of metallic arsenic, which, calculated for the whole organ, gave 0.84 grains of arsenious oxid for the entire liver.

The second experiment points to the fact that larger amounts of arsenious oxid than of sodium arsenite can be taken without causing symptoms of poisoning. This is what would be expected on account of the greater insolubility of the former. Again, as would be expected, the amount that the system will tolerate is much larger in the latter case.

When arsenic was given as sodium arsenite, two grains, in divided doses, caused symptoms of arsenical poisoning, while, when arsenic was given as arsenious acid, 3.5 grains were taken at a single dose without serious inconvenience. The amount deposited in the liver was large, very possibly up to the full capacity of that organ to retain the poison.

Exophthalmic Goiter in Mother and Daughter.—Kronthal (*Berliner klin. Wochenschr.*, 1893, No. 27, p. 650) has reported the case of a girl, twelve years old, who presented palpitation of the heart and tachycardia, protrusion of the eyeballs, enlargement of the thyroid gland, and infrequency of winking. To these symptoms there subsequently became added hallucinations and hysterical manifestations. The mother of the girl, forty-five years old, presented tremor upon exertion, palpitation and tachycardia, headache, sacral pain, prominence of the eyeballs, and infrequency of the act of winking. The throat felt tense, but there was no appreciable enlargement of the thyroid gland.

CLINICAL MEMORANDA.

TRAUMATIC ANEURISM OF THE THIRD DIVISION OF THE RIGHT SUBCLAVIAN ARTERY, TREATED BY INCISION AND DOUBLE LIGATURE; HEMORRHAGE CONTROLLED BY PROVISIONAL LIGATION OF THE FIRST DIVISION OF THE SUBCLAVIAN AND PRESSURE ON THE AXILLARY ARTERY.[1]

BY ALBERT B. MILES, M.D.,
PROFESSOR OF SURGERY, MEDICAL DEPARTMENT TULANE UNIVERSITY OF LOUISIANA, NEW ORLEANS, LA.

JOSEPH MCG., a colored man, of good health and habits, aged thirty-seven years, on the 9th of December, 1892, received a gunshot wound of the right subclavian artery. The bullet, of thirty-eight caliber, was delivered in front at very short range, and, entering just above the clavicle and passing directly through, lodged under the skin of the back. The hemorrhage at the time of the accident must have been considerable to furnish a pretext for the patient's startling statement, to which with consistency he still adheres, that he lost "one gallon of blood." The character of the hemorrhage was that of a spurting stream. The hemorrhage was arrested by a styptic compress of alum, soot, and cobwebs. On the second day after the accident the wound bled twice, and again on the tenth day. These hemorrhages were arrested by the successful method practised in the first instance. On no subsequent occasion was the hemorrhage as profuse as at the time the wound was received. This fact may be explained by the acute anemia resulting from the first hemorrhage.

About ten days after the accident the patient observed a pulsating tumor in the track of the ball. This grew gradually, in the course of six weeks, to the size of a lemon. During a journey of several hundred miles from his home in Northern Louisiana to the hospital, the aneurism rapidly increased to the size of an orange. Upon admission into the Charity Hospital the tumor occupied much of the cervico-clavicular region. All of the aneurismal signs were present, the pulsation, however, being rather feeble. The right upper extremity was edematous and the pulse was absent at the wrist. The member was partially paralyzed, and had been so from the moment of the accident. The patient was quite asthenic and his pulse beat about one hundred per minute. The evidences of anemia were marked. The pressure-symptoms were urgent and entailed loss of sleep and much suffering.

The diagnosis of the condition was simple. The copious quantity of blood described could have come only from the subclavian artery. No smaller vessel could have delivered such a quantity of blood in the given time. The amount lost in a short while gave evidence of a large arterial wound. The size of the opening and the easy escape of blood made it less likely that the arterial coats were, in any way, involved in the aneurismal swelling. The direction of the bullet's track enabled us to locate the wound about the middle of the third division of the subclavian, the most favorable site for ligation. The rapidly increasing size of the tumor, its irregularity of outline and the feebleness of pulsation strengthened the belief that the aneurismal changes were going on outside of the artery. Then we had good reason to believe that the arterial coats near the wound would bear the ligatures indicated in the treatment of a traumatic aneurism; and we felt convinced by the conditions presented that there was easy room for the application of the double ligature in the third division of the artery. We determined at once to perform this operation, which, however, was only practical after incision of the sac and turning out the overlying clots. The difficulty of securing the bleeding ends of the subclavian artery, under the conditions presented, can only be properly appreciated by one who has either himself made or witnessed the attempt.

In 1875, in the closing days of the renowned case of right subclavian aneurism which Dr. A. W. Smyth, then House-Surgeon of the Charity Hospital, had successfully treated by the ligation of the innominate, common carotid, and vertebral arteries, nearly eleven years previously, the writer had the opportunity of witnessing an attempt somewhat like that contemplated in the present case. After the lapse of nearly eleven years, according to the published report, the aneurism returned in the original site. An abscess had formed in proximity to the aneurism, and the aneurismal sac had ruptured into the abscess-cavity. In this exigency an attempt was made to incise and evacuate the aneurismal sac and secure the feeding vessel. The hemorrhage was absolutely uncontrollable and baffled the attempt. Need we say, in passing, that this case of right subclavian aneurism, just cited, treated by a New Orleans surgeon, and in our Charity Hospital, twenty-eight years ago, still stands without a rival in the surgery of the arteries.

Recollecting the lesson impressed by that case, we determined to adopt all possible safeguards against hemorrhage. In the patient's anemic state, the loss of much blood would have speedily ended his life. It was impossible by pressure on the proximal side to control the aneurismal pulsation, owing to the deep position of the artery; so a provisional ligature was placed on the first division of the subclavian. With this ligature in the hands of an assistant, and a pad in the axilla to control a reverse current, the sac was incised freely and the clots removed. The wound of the artery was revealed, the bullet having torn away one-half of the circumference of the vessel. The artery was ligated on either side of the wound. The loss of blood was not considerable, and most of that which escaped came from the large and irregular sac of the aneurism. The mode of procedure adopted by no means secured a bloodless operation, but greatly lessened the hemorrhage and made ligation easily practicable.

The shock of the operation was very great. The hot saline solution, in the strength of one dram of common salt to the pint of sterilized water, was employed by transfusion, and the patient was carried over the crisis. The operation was performed in the Surgical Clinic of the Medical Department of the Tulane University of Louisiana, with the assistance of Dr. J. D. Bloom, Dr. H. J. Scherck, Dr. Wm. E. Parker, and Mr. Marion Souchon, the Interne of the Surgical Service. The

[1] Read at the Annual Meeting of the Louisiana State Medical Society, May 10, 1893.

aneurismal sac was packed with gauze and every possible precaution taken against sepsis. On the afternoon of the same day the following points were recorded: Temperature, 99° F.; pulse, 140; respirations, 40 per minute. On the second day the temperature reached 101° F., but thereafter never exceeded 99.5° F.

The symptoms of shock after the operation were extreme, and necessitated active hypodermatic stimulation. In the afternoon of the first day collapse seemed imminent. The pulse was 140 and the respirations 40 per minute, and the surface was bathed in perspiration. At this juncture, the hypodermatic injection of one-sixtieth of a grain of atropin sulfate was practised and very promptly arrested the exhausting drain. The very happy effect of this special stimulant, which I desire to commend in such cases, turned the scale of the patient's chances, and from that time he began to improve.

Food and stimulants by the mouth and rectum were employed guardedly with the view of maintaining the circulation at the lowest ebb compatible with the necessities of the general nutrition.

The operation-wound for applying the provisional ligature healed primarily; the open aneurismal sac healed gradually by granulation without any untoward symptoms. On May 7th, all the wounds were perfectly healed. Pulsation reappeared in the radial artery on the 6th of March, and has since remained, but is feeble. The edema has subsided. The paralysis resulting from the wounding of nerves of the brachial plexus remains, but the usefulness of the limb is daily improving. The patient was discharged from the hospital on the 10th of May, all the local conditions presenting the evidence of a complete cure.

The fortunate location of the wound of the artery, the conditions that favored ligation on either side of the opening, and the methods employed in the control of hemorrhage during the operation were all circumstances favoring the successful ending of this case.

A CASE OF RESUSCITATION OF THE NEWBORN.

By A. H. P. LEUF, M.D.,
of Philadelphia.

The following case seems to me of sufficient general interest as showing what can be done by perseverance in the saving of the lives of the newborn.

On February 13, 1892, I was called to see a young married woman, a housewife, who was eight months pregnant with her first child. Her temperature was 104° F. She complained of backache, general soreness, sore-throat, coryza, anorexia, emesis, and diarrhea. She also had a commencing papular eruption of the face. On the following day (the 14th) the eruption was well marked and undoubtedly rubeolous. She had twelve liquid stools this day up to noon. There had also developed a racking cough. The temperature was 104° F. In the evening her temperature had dropped to 103° F.; she had slept, and was slightly better. On the next morning (the 15th), with the eruption fading from the head and neck, but more prominent upon the arms and belly, she complained of lancinating abdominal pains since midnight. There were no discernible fetal movements. The temperature was 101½° F.; the pulse 128. In the evening there was a discharge of a little blood from the vagina, followed by nagging pains at intervals of from five to ten minutes. The temperature was 103½° F.; the pulse full and strong. On the following morning (the 16th) labor set in; the os was well dilated, the membranes protruded, and the head was within easy reach. I noticed, by palpation and inspection, distinct fetal movements on the right side near the fundus, but these the mother did not feel. I saw the patient again at noon. The membranes ruptured at 12.50 P.M. The head was in the L.O.A. position. The pains came oftener and were effective, until the head was upon the perineum, at 4 P.M., after which time the pains were weak and lasted only a few moments at a time. I now gave quininæ sulph., gr. v, and later another dose, following this with ʒj of Squibb's fluid extract of ergot. Labor began again in earnest about 6.05 P.M., and the head was expelled at 6.45 P.M.

I found the cord twice coiled around the neck and so short that it was taut. There was no pulsation. The head and face of the child were cold and the skin had a macerated appearance. I tied one of the loops surrounding the neck with two tapes and severed the cord between them. I now rapidly delivered one shoulder and then the other, and extracted the child without waiting for a pain. The uterus contracted well. The mother was directed to keep her hand upon it and tell me if it became soft; but I believed that the ergot and quinin would be answerable for this, and they were.

I then attended to the child, trying various methods of artificial respiration, without result. There was no heart-beat, no respiration, no sign of life in the perfectly limp body. There was not the slightest reaction to douches and plunges of hot and cold water, or to flagellation. I also faithfully tried Sylvester's method of artificial respiration, without any effect. The child was also thrown up repeatedly for a foot or more and caught under the arms as it descended, with the same result, though this method had served me well under similar circumstances when the Sylvester method had failed.

After the lapse of nearly thirty minutes in vain efforts at resuscitation by these various methods, I laid the child down on a woolen cloth, with its face up and head well back. A clean handkerchief was then spread over its mouth and nostrils. With the thumb and index finger of my right hand I held the nostrils shut, while my left hand partly surrounded the chest. The child's chin having been depressed and the tongue pulled forward, I blew into the child's mouth with moderate force until I met with some resistance. At the same time the chest expanded and the belly protruded. As I withdrew my mouth my left hand compressed the chest from side to side, as well as from before backward, while the belly—at least its upper part—was compressed by my wrist. Of course, during this enforced expiration I relaxed my hold upon the nostrils, withdrew the pressure of my hand and wrist from the chest and belly, and again applied my lips to those of the child to force in more air. This proceeding was repeated as regularly as possible, twenty-five to thirty times per minute. After several minutes there was occasionally a faint cardiac beat discernible with the stethoscope. This recurred at intervals of several seconds. In a few minutes more there was a gasp and a spasm of the lips, the latter being distinctly perceptible in contact with my own lips

through the linen. Another gasp did not follow for at least two minutes, though the heart-beats were gradually becoming more frequent, and the lips and cheeks began to assume a pinkish tinge. Other gasps followed at seemingly rather lengthy intervals, each becoming shorter, until there was only one minute's interval between the ninth and tenth gasps by actual time, the father of the child holding the watch before me. The gasps recurred at intervals of thirty seconds, and then more rapidly, until irregular breathing was established. The forced respiration was, nevertheless, continued until voluntary inspirations appeared every three or four seconds. At this time the breathing was about as follows: A gasp (almost a hiccough); quiet for five seconds; and then an inspiration; another in three seconds; another in two seconds; a gasp in two seconds—and so on for some time. The breathing gradually became more regular, and was watched by the father.

Attention was now paid to the mother. The placenta was found in the vagina and extracted. A binder was applied to below the hips, with a hypogastric pad. The vulva was greased liberally with lard to allay itching, which it did at once. The perineum remained intact, not even the fourchet being torn.

The child was undersized, having been one month prematurely born. It was greased all over with lard and the eyes were washed. The umbilicus was dressed with a plain piece of linen cloth, a belly-band was applied, and the child rolled up in warmed cotton. Meconium had been expressed by the respiratory maneuvers. The maternal temperature after the delivery was 98½° F.

The mother and child progressed nicely, the former to complete recovery, but not without a reappearance of the eruption after labor, as was to have been expected. The child developed a characteristic rubeolous eruption, with slight cough and considerable coryza, on the twelfth day (February 27th). He received no treatment other than a little aromatic tea, mother's milk, and careful guarding against exposure to cold. On the 29th the eruption disappeared. The child is now strong and well, in the latter half of his second year.

2353 NORTH SEVENTEENTH STREET.

SUCCESSFUL NERVE-STRETCHING FOR THE CURE OF SCIATICA.

BY JAMES KENNEDY, M.D.,
OF SAN ANTONIO, TEXAS.

WM. C. M., forty-two years old, a machinist, some twelve years ago was engaged in moving a house when, owing to the occurrence of an accident, the supports of one corner gave way, and he was crushed to the ground under the hand-spike that he held. He was confined to his bed on account of this wrench, as he termed it, for about three weeks, at the expiration of which time he recovered sufficiently to resume his duties. Some months after the occurrence of the accident he felt pain over a region corresponding to the track of the great sciatic nerve, but most marked over the point where this nerve emerges from the pelvis. These attacks, which at first occurred at intervals of many months, became much more frequent, and increased in severity until April, 1893, when he was seized with the most severe attack from which he had ever suffered, being unable to turn in bed or make any movement of the body whatever, on account of the intensity of the pain. On attempting to turn over for the purpose of permitting an examination, he shrieked in agony. According to his own statement, all remedies had been tried, and some little improvement had followed the use of each, but no means of cure had yet been found.

I did not care to follow in the beaten track which so many had pursued in the treatment of his case, and which had yielded such poor results, so I proposed nerve-stretching as a possible means of cure.

He acquiesced in my proposition, and the operation was performed in the following manner: The patient was anesthetized, and after due aseptic precautions had been taken, an incision four inches in length was made through the skin and fascia on the posterior surface of the thigh, just a little above its middle, and the muscles exposed. The biceps and semi-membranosus were gently separated by means of the finger, and the nerve, thus exposed, was lifted out through the wound and moderately forcible traction made upon either end, and then returned. The wound was closed antiseptically, and perfect union took place by first intention within a few days. A remarkable feature of the case is that the pain immediately subsided, and only the slight discomfort incident to the incision remained. Recovery was complete, and remained to the present time (July 10, 1893).

MEDICAL PROGRESS.

Trephining for Subdural Hemorrhage, followed by Osteoplastic Resection.—RIEGNER (*Deutsche medicin. Wochenschr.*, 1893, No. 28, p. 667) has reported the case of a child, six years old, who fell from the height of the second story of a dwelling, losing consciousness. The pulse was slowed, and a hematoma, as large as the palm of an ordinary hand, formed in the left temporal region, and a second, as large as a plum, formed in the right parietal region. There was distinct paresis of the right half of the body, including the face. This was not so marked a day later, the loss of consciousness likewise not being so profound. The child could be aroused by loud cries, but spoke no word. By the fourth day the blood-swellings were sufficiently absorbed to permit of the recognition of a fissure of the skull in the left temporal region, a little in front of the external auditory meatus and reaching to the sagittal suture. Clonic convulsions took place in the muscles of the right side of the face, and a day later in those of the extremities of the same side, at times continuing uninterruptedly for hours. At the same time choking of the optic disc could be seen to have begun; consciousness had been quite restored, but speech remained entirely in abeyance. With the idea of relieving a subdural hemorrhage in the left frontal and central regions, resulting from rupture of the middle meningeal artery, trephining was undertaken on the sixth day, but the hemorrhage was found to have taken place beneath the dura, upon opening which fluid and clotted blood and débris of cerebral tissue were evacuated. Pulsation of the brain, which had previously been absent, soon returned. The wound was gently packed with iodoform-gauze and the flaps only partially sutured. The symptoms at once receded, the motor aphasia, however, but slowly.

A proposition at this time to close the defect in the skull by resection of the adjacent bone was declined. The child's vocabulary grew until he ultimately acquired a considerable range of language. A year and a half after the accident the parents came with a request that operative measures be undertaken, as the wound manifested no tendency to close spontaneously. Accordingly, a segment of bone was removed from the skull in front of the defect, which it was made to close. A little additional skin was required and was transplanted from the thigh. The result was in all respects a satisfactory one.

Epithelial Pearl-tumor of the Iris Following Implantation of an Eyelash in the Anterior Chamber.—At a recent meeting of the Ophthalmological Society of the United Kingdom, Cross and Collins (*British Medical Journal*, No. 1698, p. 118) reported the case of a boy, eight years old, who presented himself for loss of vision in the right eye, seven months after a wound of the eye by a piece of wire. The eye was free from inflammation, the tension was normal, and there existed a traumatic capsular cataract, with posterior synechiæ. At the upper inner segment of the anterior chamber was a small nodule, from which an eyelash passed downward in front of the iris. An operation was undertaken to remove the eyelash and, if possible, the small nodule, which was diagnosticated to be an epithelial implantation-cyst growing from the root-sheath of the cilium. The eyelash was readily removed, but the cyst was closely adherent to the iris, which, in turn, was so fixed by adhesions that it could not be removed entire, but came away piecemeal. The wound healed readily. Two months later the tumor had commenced to grow again. The patient was lost from observation for nearly a year, when he returned with great irritability, lachrymation, and photophobia of the right eye. The tumor had increased greatly in size, and as the left eye was sympathetically irritated, and the first operation had been so difficult, the right eye was enucleated. The tumor was found to be surrounded by pigmented iris-tissue and free from cornea, vitreous, and ciliary body. The mass situated in the iris proved to be a cyst, with opaque, white contents, and lined by laminated epithelium, the cells in contact with the iris-tissue being the best developed, the innermost ones being flat and scaly. The contents of the cavity consisted of fat-globules and polyhedral cells, in which no nucleus was stained. They were probably epithelial cells undergoing degeneration. The papillary border of the iris was united by newly-formed fibrous tissue to the anterior capsule of the lens.

Successful Extirpation of the Prostate Gland.—At a recent meeting of the Royal Society of Physicians of Vienna, Prof. Dittel (*Internationales klin. Rundschau*, 1893, No. 25, p. 938) reported the case of a robust farmer, thirty-two years old, who complained only of hematuria. Careful examination failed to detect the presence of a stone within the bladder, but upon manipulation of the abdominal wall a tense, oval tumor could be felt, while through the rectum the prostate was found considerably enlarged. The tumor persisted after the removal, by means of the catheter, of all urine from the bladder. On endoscopic examination a bulbous prominence was seen upon the right wall of the bladder, from the surface of which blood flowed. The bladder was opened through a supra-pubic incision and the bleeding prominences removed by means of the curet. An incision was now made from the coccyx to the anus and continued around the latter; the coccyx was removed; an incision was made through the rectum upon the right side; the capsule of the prostate was opened and the gland enucleated. The growth looked like a fibroma, but the microscopic appearances did not conform to those of any known type of neoplasm. The cavity created was packed with iodoform-gauze and the bladder was drained. Upon filling the bladder none of the fluid used escaped, but in the course of a few days the gauze emitted a urinous odor. The wound, however, grew progressively smaller. The success of the operation is ascribed to the anatomic fact that the urethra did not pass through the prostate, as it commonly does, but was superimposed upon the gland.

Amblyopia of Dental Origin.—At a recent meeting of the Paris Society of Ophthalmology, Despagnet (*Le Mercredi Médicale*, No. 24, 1893, p. 294) reported the case of a woman, twenty-six years old, in which the right eyeball had been enucleated on account of a neoplasm, probably of tuberculous origin. For three months vision had been failing in the left eye, the acuity being reduced to 1/xx. There was also complete external ophthalmoplegia. The fundus oculi presented only dilatation of the veins. Tuberculosis of the brain was suspected, especially as hysteria could be excluded. Three weeks after the first examination a slight suffusion was observed at the outer margin of the pupil. On examination of the teeth the second upper bicuspid upon the right side was found to be carious, and the adjacent inflamed gum presented a small fistula. The supraorbital and the infraorbital nerves were not tender upon pressure, but at night the patient felt pain upon the corresponding side of the head. The tooth was at once removed, and within forty-eight hours the visual acuity had improved to 3/x. The improvement was progressive. A month later a small area of necrosis was found upon the upper jaw; this was removed and a small quantity of pus evacuated. Eight days later the visual acuity had returned to normal.

Hydatid Cyst of the Lung opening into the Pleura.—At a recent meeting of the Paris Society of Surgery, Delangeniére (*Rev. gén. de Clin. et de Thérap.*, No. 24, 1893, p. 381) reported the case of a man, twenty-five years old, who three years before was suddenly seized with violent pain in the left side of the chest, which disappeared in the course of a few days. Some eighteen months later he was again seized with pain upon the same side, but at a different point; and a generalized urticaria developed. Soon the signs of a pleural effusion appeared, with marked dyspnea and displacement of the heart. Upon puncture, more than three pints of greenish fluid were evacuated; upon a second puncture, a few days later, more than two pints of purulent fluid were evacuated. The patient declining resection of the ribs, a simple opening was made and flaky membrane and the debris of an hydatid cyst evacuated, and drainage was instituted. In the course of two months numerous hydatids were thus expelled, but finally suppuration set in and hectic fever developed. Finally the sixth, seventh

and eighth ribs were resected for a distance of 4½ inches, and adequate drainage provided for, with the result that in the course of a couple of months complete recovery ensued.

Nephrectomy for Ureteritis.—JAMES ISRAEL (*Berliner klin. Wochenschr.*, 1893, No. 27, p. 641) has reported the case of a man, twenty-eight years old, who for eight years had attacks of left-sided renal colic recurring at intervals of three weeks, with pain in the course of the ureter in the intervals between the paroxysms. Hematuria was frequent and red blood-corpuscles were at all times to be found in the urine. A definite history of gonorrhea could not be obtained. In the belief that the trouble was due to a renal calculus, the kidney was exposed and incised, but no foreign body was found, although the pelvis and calices were dilated. The wound in the kidney was closed by means of five catgut sutures and united by first intention. The operation was followed by no improvement in the man's condition, so that, as soon as recovery had taken place, the ureter was exposed and found to be inflamed, thickened, adherent, and stenotic. At a loss as to how to proceed, the wound was left open, but as the colic persisted, the kidney was extirpated two days later. The removed organ was of normal size, but, upon section, displayed marked hydronephrotic dilatation of pelvis and calices. The relief was immediate and maintained.

The Prognostic Significance of the Pupillary and Patellar Reflexes in the Algid State of Cholera.—At a recent meeting of the Société Médicale des Hôpitaux, GALLIARD (*Rev. gen. de Clin. et de Thér.*, 1893, No. 26, p. 414) reported the results of examinations of the pupillary and patellar reflexes in 161 cases of cholera in the algid stage, of which 75 recovered and 86 died. Mobility of the pupil or a slight degree of paretic sluggishness of contraction was of no significance. Immobility of the pupil, on the contrary, indicated gravity of prognosis. Exaggeration of the patellar reflexes often preceded an unfavorable termination; the preservation of the normal reflexes was a more favorable indication; their abolition was observed in some cases that recovered, and seemed to be of no special significance. When pupillary and patellar reflexes where both preserved the chances of recovery were as two to one; with their abolition the chances of a fatal termination were as two to one.

Auscultatory Percussion in the Diagnosis of Fractures of Bone.—VAJANA (*Rif. Med.; Wien. med. Presse*, No. 28, 1893, p. 1116) has found that if a stethoscope be applied over a long bone, while at the same time percussion is practised at a different point by means of a plessimeter and hammer, a distinct and rather disagreeable sound will be heard. If, however, the continuity of the bone is broken, the sound loses its disagreeable character as soon as the line of fracture is passed by the percussing instruments. The difference becomes more evident if a comparison be made with a corresponding part of the opposite side of the body.

Sudden Death in a Case of Hysterical Vomiting.—ROBINSON (*Lancet*, No. 3641, p. 1380) has reported the case of a woman who, from the age of puberty, displayed varied manifestations of hysteria. After marriage she bore two children, and the hysterical symptoms remained in abeyance; but after some time obstinate vomiting set in and continued to a fatal termination, which occurred during the night at the end of some eighteen months, several hours after a light meal. During life there was no evidence of organic disease, and after death there was found little abnormality beyond dilatation of the stomach.

THERAPEUTIC NOTES.

Sero-therapy of Pneumouia.—LAVA (*Giorn. della R. Acad. di Med. di Turino*, January, 1893; *Rev. des Sci. Méd.*, etc., No. 83, p. 112) has reported the results arrived at from a study of ten cases of pneumonia treated by injections of blood-serum and of extracts of the viscera of pneumonic animals. The injections occasioned no reaction, immediate or remote. No subjective discomfort followed the injection of the serum or extracts of the viscera of rabbits, although transitory disturbance followed injection of the serum of dogs. The injections exerted no immediate decided influence upon the temperature, although there was a progressive decline. The frequency of the pulse was at once and permanently diminished. The frequency of respiration underwent a similar change. The crisis followed soon upon the injections, and was limited in duration. Convalescence was usually speedy and recovery resulted without complication.

Chlorobrom for Sea-sickness.—After an extended trial of chlorobrom in marine practice, the patients remaining under observation for some months, LEDINGHAM (*Lancet*, No. 3643, p. 1515) pronounces this the most satisfactory remedy yet produced for the treatment of sea-sickness. The agent was found especially valuable in those cases in which the patients, though not suddenly and violently sick, were in a state of chronic misery, with headache, nausea, great depression, sleeplessness, and anorexia. As a rule, the nervous symptoms disappeared and the patients gained refreshing sleep and generally made a rapid recovery. The ease of administration, the safety of the remedy, and the complete absence of objectionable symptoms are points of great importance. The solution was also found exceedingly useful in many cases of insomnia and nervous derangement.

Oil of Gaultheria for Alopecia.—At a recent meeting of the Paris Society of Dermatology, HALLOPEAU (*Wien. med. Presse*, No. 24, p. 943) recommended employment of oil of gaultheria in the treatment of alopecia. The agent proved far superior to oil of cinnamon. It did not cause irritation, so that the effect must be ascribed to a destructive influence upon the cause of the condition. The best results were obtained from a mixture containing equal parts of ether and oil of gaultheria.

For Myalgia.—

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 19, 1893.

INSANITY FROM INTOXICATION AS A DEFENCE TO CRIME.

THE rule laid down by the Supreme Court of Kansas concerning the responsibility of a person who, at the time of the commission of an alleged crime, has sufficient mental capacity to understand the nature and quality of the particular act or acts constituting the crime, and the mental capacity to know whether they are right or wrong, that he is generally responsible if he commits such act or acts, whatever may be his capacity in other particulars, was forcibly challenged in the case of State *v.* O'Neil, just reported (33 Pacific Reporter, 287). The theory of irresponsibility from an irresistible or uncontrollable impulse was ably presented. Several authorities were cited and the Court also referred to a lengthy article "On the Legal Aspect of Insanity," published in 1 N. W. Law Rev. 1, which stated, among other things, that "it would be difficult to crowd into the same compass more erroneous ideas than are found in the charge of the Court in the GUITEAU case." The Court said that it had examined these authorities and had also read similar articles in the magazines upon legal or forensic medicine, which support and even go further than the views expressed in the Law Review.

Some of the articles in the medico-legal journals assert that all crimes result from heredity, and, therefore, that all persons committing alleged offences should be considered irresponsible, and be subjected to treatment for disease only; not for crime. The decisions cited were called sporadic cases, and against the overpowering weight of authority. As declared by this Court early in the State's history: "It is possible that an insane, uncontrollable impulse is sometimes sufficient to destroy criminal responsibility, but this is probably so only where it destroys the power of the accused to comprehend rationally the nature, character, and consequences of the particular act or acts charged against him, and not where the accused still has the power of knowing the character of the particular act or acts, and that they are wrong. Indeed, it would seem dangerous to society to say that a man who knows what is right and wrong may, nevertheless, for any reason, do what he knows to be wrong without any legal responsibility therefor. The law will hardly recognize the theory that any uncontrollable impulse may so take possession of a man's faculties and powers as to compel him to do what he knows to be wrong and a crime, and thereby relieve him from all criminal responsibility. Whenever a man understands the nature and character of an act and knows that it is wrong, it would seem that he ought to be held legally responsible for the commission of it, if in fact he does commit it." And in a later case the Court adopted the views thus expressed upon uncontrollable impulse. Nor is it now inclined to adopt the theories of psychologic enthusiasts to overthrow the long-established criminal practice in this class of cases, which is based on human experience from earliest times. The Legislature might, very appropriately, pass an Act permitting the State or the accused to have the question of insanity tried before the main trial upon the information or indictment. In such a case a jury of physicians might be required to be summoned to determine the sanity or insanity.

In the case under consideration evidence was offered upon the part of the accused showing that he had inherited an appetite for intoxicating liquors; that he had indulged that appetite during life; and that the habit for drink had grown upon him so that he had the reputation of being an habitual drunkard. It was further insisted, the evidence tended to prove, that at the time of the killing he was insane from alcoholism. The Court, however, instructed the jury, among other things, that voluntary intoxication is no defence to murder in the first degree, unless such in-

toxication should be so extreme as to rob the mind of the power of premeditation and deliberation. Hence, if it was found that the accused committed the act of killing as charged, and that at the time that he did so he was in a state of intoxication caused by his voluntary action, he was guilty of murder in the first degree, unless it should be further found that such intoxication was so extreme as to prevent his mind from the exercise of deliberation or premeditation; in which latter case he would be guilty of murder in the second degree, or manslaughter in some of the degrees. If the jury should believe from the evidence, beyond a reasonable doubt, that the accused did the killing at the time that he was so drunk as to be incapable of entertaining deliberation and premeditation, and also was incapable of entertaining the elements of purpose and malice, and that he had no previous knowledge that when intoxicated that he was liable to commit acts of violence upon his wife, whom he was charged with murdering, or others, as a consequence of such drinking, it could not find him guilty of murder in either the first or second degree.

When a person is shown to have been in the habit of becoming intoxicated, and it is further shown that when intoxicated he is likely to commit acts of violence upon his fellows, and endanger their lives or safety, and such person is shown to have knowledge of such fact, and, having such knowledge, voluntarily becomes intoxicated, then, and in such a case, such person would be as fully and entirely responsible for acts of a criminal nature committed by him while in such state of intoxication as though the act had been committed by him while not intoxicated. When insanity is set up as a defence to crime committed, the rule that the jury must ever keep before their eyes and minds in determining the responsibility of the accused is this: "Was the accused, at the time of doing the act complained of, conscious of the nature of his act, or did he know that it was wrong to do it?"

BISHOP, in his work on *Criminal Law*, says: "When a man voluntarily becomes drunk, there is the wrongful intent; and if, while too far gone to have any further intent, he does a wrongful act, the intent to drink coalesces with the act done while drunk, and for this combination of act and intent he is liable criminally. It is, therefore, a legal doctrine, applicable in ordinary cases, that voluntary intoxication furnishes no excuse for crime committed under its influence. It is so even when the intoxication is so extreme as to make the person unconscious of what he is doing, or to create a temporary insanity." "Again, the law holds men responsible for the immediate consequences of their acts, but not ordinarily for those more remote. If, therefore, one drinks so deeply, or is so affected by the liquor that for the occasion he is oblivious or insane, he is still punishable for what of evil he does under the influence of the voluntary drunkenness. But, if the habit of drinking has created a fixed frenzy or insanity, whether permanent or intermittent—as, for instance, delirium tremens—it is the same as if produced by any other cause excusing the act; for whenever a man loses his understanding, as a settled condition, he is entitled to legal protection, equally whether the loss is occasioned by his own misconduct or by the dispensation of Providence." If drunkenness produces insanity through delirium tremens or *mania a potu* or other disease, and the accused at the time of the homicide has no sufficient capacity or reason to enable him to determine between right and wrong as to the particular act he is doing, or has no power to know that the act is wrong and criminal, he would not be responsible. In cases of delirium tremens or *mania a potu*, the insanity excuses the act, the frenzy being, not the immediate effect of indulgence in strong drink, but a remote consequence superinduced by antecedent drunkenness.

A HYGIENIC SYMPOSIUM.

THE completion of the fiftieth year of the doctorate of MAX VON PETTENKOFER has been celebrated by the publication of a volume of over seven hundred pages, consisting of original contributions from his pupils and colleagues. The name of the master is familiar to all students of physiology and hygiene; it is indissolubly associated with important analytic processes and with ingenious speculations as to the propagation of disease, and all can join in the wish, expressed in the dedicatory preface, that the great teacher may continue many years to be an ornament to science and a benefactor to humanity.

Apart from the appropriateness of the testimonial and its superiority over a mere collection of laudatory speeches, the volume has value as showing the trend and results of the school of hygiene that PETTENKOFER has developed. He has long been known as the advocate of the "localistic" theory

of the propagation of infectious disease. His researches on the movement of the subsoil water and its relation to the development of enteric fever and cholera have been extended by many of his pupils, and in his recent essay, "The Present State of the Cholera Question," he has brought all the resources of his long experience, scientific methods and brilliant style to bear in support of his views.

The volume contains twenty-eight original contributions, covering almost the entire field of hygiene. Bacteriology receives a comparatively small share of attention, and there is very little reference to analytic methods. With the exception of a paper by Buchner on the self-purification of streams, there is nothing on the subject of water-supply. Some American food-products are treated with suspicion and criticism. Hasterlik refers to a charge that horse-meat is substituted for beef in the imported canned goods, but in the examination of seven of the most prominent brands, finds no such substitution. Incidentally he gives methods of distinguishing between beef and horse-meat that will prove of value in general food-inspection.

Sendtner presents a summary of the more important results of the inspection of food and drugs in Munich. Among these may be noted the detection of the employment of sulfites for preserving canned vegetables. Attention is called to investigations that have shown that sulfites are injurious. Some cosmetic articles contained lead or mercury or both. Over two thousand samples of enamelled cooking utensils have been examined since 1884, sixty-five per cent. of which were found to yield to boiling vinegar marked amounts of lead. As lead is one of the most insidious and frequent sources of chronic poisoning, this record has great practical interest. As might be expected, the cheapest goods were found to be most dangerous. American lard is severely criticised. Sendtner found a large proportion of the samples to be adulterated with cotton-seed oil, and to be objectionable in taste and odor. The latter statement is rather surprising. It is also stated that oleomargarin is at present of much inferior quality than formerly, and the hope is expressed that some means may be secured for improving the keeping qualities of cocoanut oil, which affords a cheap and wholesome fatty food.

Dr. Franz Spaet contributes a lengthy statistical study of enteric fever in central Bavaria from 1870 to 1890. The etiologic influences are considered in detail and, as might be expected from a pupil of Pettenkofer, the water-carriage theory is declared to be disproved in almost every instance, while fluctuations of the subsoil water are looked upon as the most striking features. Of the same tenor are two articles on enteric fever in Munich, one by Schuster relating especially to the mortality in the the army barracks, and another by Eisenlohr and Pfeiffer relating to the mortality in the entire city from 1888 to 1892. The paper by Schuster furnishes a highly interesting summary of the course of the disease since 1851. From then until 1881, with occasional abatements for a year or two, Munich has had an annual death-rate from this disease of from one to three per thousand. In 1881 a striking decrease occurred, the ratio falling to less than two-tenths per thousand per year, and the figures have become more favorable each year, so that the city, once truly designated as a "typhoid nest," has become practically free. It seems to be demonstrated that this improvement has not depended on the improvement of the drinking-water. A partial reform in that respect, secured in 1865, was not followed by material change in the death-rate from enteric fever, and the marked fall in mortality that has continued to the present time began two years before the general reconstruction of the water-supply. It appears that in Munich, at least so far as concerns enteric fever, the improved sanitary condition has depended upon improved drainage and municipal management rather than upon the water-supply. In fact the authors of the papers under notice lay much stress upon the beneficial results of the establishment of central abattoirs, and the abolition of the private slaughter-houses.

It is in this field of hygienic discussion that the features of the Munich school are most strongly exhibited, especially in contrast to that of the Berlin school. Pettenkofer and his followers have never given a hearty consent to the theories of the microbic origin of disease. Forced by unanswerable demonstrations to accept some of the positions taken by Koch and his school, they have appeared rather as critics than as propagandists of such doctrines. The papers here quoted are able and exhaustive, the statistical data are trustworthy and abundant, and, whatever may be our views as to the issues involved, there seems to be no doubt that enteric fever and similar diseases are not infrequently conveyed by other channels than polluted water, and further, that water may be highly contaminated, as judged by certain technical standards,

and yet cause no disease. The critical attitude of the Munich school in respect to the general tendency of sanitarians has, doubtless, a scientific value. It restrains hasty generalization and superficial investigation, and forces the closest inquiry into the data of each case.

In an essay on the self-purification of streams, BUCHNER shows that light has a decided germicidal power. Even diffuse daylight in autumn is sufficient to kill *B. typhosus*, *B. pyocyaneus*, and *B. coli* in five hours. These facts must have great importance in connection with the subject of water-purification by storage, and tend to show that in spite of the somewhat alarming statements to the contrary, a sewage-polluted river may, by certain methods, be at least greatly improved.

DR. LUIGI MANFREDI contributes an elaborate paper on the food of the poor in Naples, in the course of which a vivid picture of the misery of the city is presented.

EDITORIAL COMMENTS.

First Aid to the Injured.—We wish to call attention to the exhibit of the St. John's Ambulance Association in the English Department of the Liberal Arts Building at Chicago. The good work of the Association is well recognized in Europe, and our young men should undertake similar means of saving life and limb in the United States. The object of this Association is (*a*) to disseminate instruction in rendering first aid to the injured; (*b*) to instruct women in home-nursing; (*c*) to deposit in appropriate localities materials (such as stretchers, hampers, splints, bandages, and dressings) for use in case of accident.

Our factories, railways, and cities are full of danger, and workmen, trainmen, policemen, and street-car conductors should, for the public good and their own safety, be thoroughly instructed in arresting hemorrhage and transporting injured people, and they should be supplied with means necessary to save life. The railroads of this country are said to lose $12,000,000 a year by accidents to life and limb. In the city of Pittsburg, in 1890, there were 440 deaths from violence out of 4200 deaths from all causes. In ten years there were 30,000 people injured in the streets of London, of whom 2000 died from these injuries.

The rich and the poor ride in railways and throng the streets of the cities, and alike they suffer because few know how to stop blood or transport a fainting, suffocated, or injured person.

The University of Chicago has placed in the Extension Department a lecturer on "First Aid to the Injured," and we hope that physicians will help to organize centers about every university that is wise enough, rich enough, and humane enough to turn a few moments from the Greek roots and comet-hunting and follow the example. There should be such a center wherever there is a police force, a railway center, a factory, a road-gang, a mining camp, a logging cabin, a yachting lake or stream, a skating park, or a place to swim.

Spelling-Reform.—The remarkable unanimity with which the medical press of the United States has enthusiastically welcomed the beginnings of spelling-reform, advocated by THE NEWS, is a hopeful sign. Journal after journal has taken the subject up, giving notice to readers that the suggested changes should be followed by the contributors, and would be followed by the editors. Our English colleagues, however, are silent, or very, very growly. *The Medical Press and Circular*, for example, calls it "a maniacal outburst," and abuses American spelling most roundly—without, of course, advancing a single reason against it. Formerly, the English have had the delightful impertinence to repeat *ad nauseam* that the sole reason for "American spelling" was simply our horrible ignorance of the proper way of spelling words. We believe that Josh Billings and his school have been seriously upbraided for the same dense ignorance by English critics. It is now too condemnably bad to have it even hinted that the greatest philologists and lexicographers and scientists advocate sensible orthography. To learn anything from America is, moreover, a bitter experience. How long the Britisher struggled against sleeping-cars and dining-cars on his railways is a funny and instructive history. "Brasses" for his luggage, you know, will still be detested, though he has infinite trouble and loses his unchecked baggage every trip. It is the part of wisdom, however, that the learned editor of the *Medical Press and Circular* chooses. Let him reiterate his detestation of the recommendations of the American Association for the Advancement of Science, of Professor Whitney, of all men and things American. But let him and his friends beware of attempting to give a single reason for their medievalistic orthography, for "there is nothing more contemptible than our present spelling, unless it be the reasons usually given for clinging to it."

The Cholera.—Contrary to expectation, fifteen cases of cholera developed among the passengers on the steamer Karamania, in New York harbor from Marseilles. Two deaths have occurred. All of the sick have been isolated and there are no fears of an extension of the disease.

It is cabled from Rome that official statistics as to the cholera in Italy show that during the week ending August 10 there were in Naples 258 cases of the disease and 121 deaths. On the island of Capri, twenty miles from Naples, there were during the same period fourteen cases and eight deaths. The disease was spreading to other coast towns.

The Marine Hospital Service has been notified by its representative at Naples that Italian emigration has been stopped.

From St. Petersburg it is announced that the intensity of the heat has caused a sudden increase of the cholera-epidemic in the infected Russian cities. In Moscow there were, on August 14, forty-seven fresh cases and sixteen deaths. The official returns, although understating the mortality from the cholera, show that the epidemic is much severer than that of 1892. In Nijni Novgorod the cholera has appeared in most virulent

form. In the week ending August 13 the fresh cases there numbered 260, the deaths 105. At Rostoff, twenty-two miles from the mouth of the Don, there have been 116 fresh cases and 50 deaths in the week ending August 13.

The Business of Registering and Indorsing Diplomas may be profitable in a financial sense to the medical schools who do it regardless of the ethical or educational fitness of the applicant, but it certainly is not very helpful to the medical profession. Men who educationally are utterly incompetent to pass proper examinations, and who were quacks in every true sense of the word, have been "indorsed" by institutions without a single test as to their acquirements or character, thence going forth to wage guerilla warfare on the profession as advertisers and perambulating quacks. Such authority should be taken from colleges.

The Gonococcus and Endocarditis.—It is announced that at a recent meeting of the Berlin Society for Internal Medicine, Leyden reported a case of gonorrhea, complicated by epididymitis and synovitis, in which endocarditis also developed. A fatal termination resulting, the autopsy disclosed the presence of gonococci in the polypoid vegetations situated upon the aortic and mitral valve leaflets, thus conclusively demonstrating a relation that clinical observation had already indicated.

REVIEWS.

The Johns Hopkins Hospital Reports. Report in Pathology, II. By J. Whitridge Williams, M.D. Baltimore: The John Hopkins Press, 1892.

This report is devoted to the record of a careful clinical and pathologic study of papillomatous tumors of the ovary and of tuberculosis of the female generative organs.

Papillomatous tumors of the ovaries are divided into papillomatous cysts, and superficial or surface papillomata. With regard to the cystic form, it is pointed out that older writers were misled by failing to distinguish glandular cystomata, and in consequence were led into error as to the origin of the cysts. Olshausen first pointed out the essential difference between cysts containing and those not containing papillary growths, but Dr. Williams does not agree with him that the papillomatous cysts in the majority of instances have an intraligamentous origin, and properly points out the further fact that the classification of Olshausen, Von Velits, and others, according to the presence or absence of ciliated epithelium, is a wholly artificial one. We are not, perhaps, in a position to explain why ciliated epithelium develops in pathologic structures; but the fact remains that under a variety of circumstances, as in the case of those papillomatous cysts, or in leg-abscess, as observed by Weber, or in renal cysts, as we have observed, epithelial cells may assume a ciliated character, and a classification based upon the presence or absence of cilia is likely to prove of little value. In summing up his own observations on the origin of these cystic tumors, Dr. Williams concludes that they may arise from the remains of the Wolffian body, from the epithelium of the oviducts, or from the germinal epithelium. The tendency to abdominal metastasis and to carcinomatous transformation is discussed at length, and the desirability of early operation is insisted upon, though the difficulties of diagnosis, especially at this period, are confessedly very great.

The superficial papillomata have been considered extremely rare, and Olshausen, in 1886, was able to collect only eight cases recorded in literature. That they are more frequent is, however, apparent from the occurrence of five cases in the experience of Dr. Williams within a comparatively short time. He was able, also, to find seven additional cases by carefully searching through the literature.

Still more important than this study of ovarian papillomata is that of genito-urinary tuberculosis of the female, which forms the second part of the book. A few writers have called attention to the frequency of these affections, but comparatively little attention has been paid to the subject by authors in general. The work of Dr. Williams, however, will go far to convince the skeptical, and enlist attention of those ignorant of the frequency of tuberculosis of the genital tract. According to the experience of various pathologists, uro-genital tuberculosis occurs in from 1 to 4 per cent. of all tuberculous women, and Nimias and Christoforis found one case in every twelve. Williams bases his own statements on the experience of 137 celiotomies. From this number may be excluded forty-six cases in which the ovaries, removed for various causes, were healthy or contained cysts. Among the remaining ninety-one cases decided and distinct tuberculosis was found in two cases, and microscopic examination revealed the lesions of tuberculosis in five additional cases in which the disease was "unsuspected." There were thus seven cases in ninety-one of all purulent cases, or tubes and ovaries removed for adhesions, 7.7 per cent. It will be seen that this agrees almost exactly with the experience of Nimias and Christoforis.

The order of frequency of different seats is as follows: Tubes, uterus ovaries, vagina, cervix, and vulva; and in each situation there may be miliary tubercles, or ulcerative or fibroid changes. Infection is by far most commonly carried through the blood, but the possibility of direct infection by coitus, by infected instruments, and in other ways, must be entertained, although it has never been proved. The treatment suggested in the case of disease affecting the ovaries and tubes is complete removal, even though peritoneal tuberculosis has also become established. From recent experience with celiotomy in tuberculous peritonitis few surgeons would be deterred by this complication, and probably many would be more inclined to operate because of it.

A Manual of the Practice of Medicine, prepared especially for Students. By A. A. Stevens, A.M., M.D., Instructor of Physical Diagnosis in the University of Pennsylvania, and Demonstrator of Pathology in the Woman's Medical College, Philadelphia. Illustrated. 8vo, pp. 501. Philadelphia: W. B. Saunders, 1893.

We can never take up a book like this without a sense of deep regret; first, that a demand for works of its character should really exist (and no observant person

can deny that such a demand does exist); and, second, that so much good work and ability should have been expended upon so thankless a task. Experience and observation have abundantly convinced us that students are the better for devoting more time to the larger text-books, and that it is the wiser to stimulate independent thought and reasoning. It were better for the student that he read much, even at the risk of some mental indigestion, than that he merely commit to memory the condensation that has been (however well) prepared for him. The careless and the absentee student cannot enter into consideration. There must be something inherently wrong in that system of education that countenances and encourages shallow study, rather than the acquirement of true knowledge; and we fear that as long as the ultimate aim of the student is permitted to be the passing of an examination by the faculty of a medical school, so long will there be a demand for quiz-books and "manuals" like this. We believe that the student would do better to take full notes of his lectures and study these carefully, and if the period of tuition is not sufficiently long to permit not only of reading that which is absolutely essential, but collateral literature as well, the period should be lengthened. A wonderful amount of material has here been compressed into a very small limit, but the student who absorbs it all will acquire a false sense of his own strength, at the expense of his mental development. How can it be possible within the limits of an article of fifteen hundred words to give an adequate description of so important a subject as pneumonia, considered from the point of view of etiology, pathology, symptomatology, complications, diagnosis, prognosis, and treatment; or in an article of two thousand words to do justice to the subject of enteric fever? It is scarcely worth while to call attention to the very few omissions that exist, and we must in fairness admit that the book is among the best of its kind. Let us endeavor to create a better class of medical students by providing them with better mental pabulum.

ON THE CHEMISTRY AND THERAPEUTICS OF URIC ACID GRAVEL AND GOUT: BEING THE CROONIAN LECTURES FOR 1892. With Additions. By SIR WM. ROBERTS, M.D., F.R.S. London, 1893.

SIR WILLIAM ROBERTS' long study of the problems of metabolism and his wide clinical experience give special value to this book. While avoiding the extreme view of some who find in uric acid a *fons et origo mali* perennial and universal, he appreciates the importance of the subject; but points out clearly the difference between gravel and gout so often ignored. The normal urates of the blood he proves to be quadri-urates, the morbid phenomena of gravel and gout arising from their conversion into uric acid (gravel) or bi-urates (gout). Urates practically form the entire renal excretion of serpents and birds, but their production in mammals is a vestigial phenomenon, indicating that mammalian evolution is not complete. Fothergill regarded it rather as a reversion. The therapeutic point is to keep the urine alkaline in subjects disposed to gravel, the alkalies chosen being preferably vegetable salts of potassium; and the most important period to safeguard being the night, when the alkaline tide of digestion cannot be depended upon for the purpose. In gouty cases, the most important measures are diet and regimen, proteids being restricted, and bread, rice, garden vegetables, salads, and fruits given freely. While chemistry cannot give any reason therefor, alcoholic and malt liquors must, on clinical grounds, be forbidden. The use of common table-salt is restricted. Alkalies have a doubtful place in the treatment of gout. If lithium carbonate or piperazin has any value, it is not due to solvent power over the material of gouty concretions. Mineral waters containing sodium salts are highly objectionable. The resort to non-sodic thermal springs is of greater benefit than using the waters at home, because "other things are *not* equal."

TRANSACTIONS OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS. Vol. V, for the year 1892. Philadelphia: W. J. Dornan, 1893.

THIS volume contains a variety of articles, most of which have already appeared in print in the medical periodicals of the past year. The article by Joseph Price, on the "Present Status of Obstetrics," gives a thorough *rêsumê* of recent opinion in this branch of practice. The reference to the treatment of eclampsia by large doses of morphin, as noted by Löhlein; the author's views on the ante-partum douche, and the tables compiled for comparison from the records of European and American maternities, are worthy of careful consideration.

The article on "Tumors of the Abdominal Walls," by Edward J. Lee, of Newark, N. J., is a most comprehensive, scientific, and original article, and seems to have called forth the most fruitful of the discussions that have been printed.

The article on "Posture in Obstetrics and Gynecology," by William Warren Potter, contains an interesting description of the various postures as accessories in diagnosis and treatment, with a complete set of photographic illustrations. The history of the discovery of the genu-pectoral position and its advantages in the application of pessaries are particularly to be noted.

A short article by J. Henry Carstens, of Detroit, on the "Technique of Vaginal Hysterectomy," is important on account of the discussion, which brings up the subject of the different patterns in clamps for the broad ligament, but in which the use of the ligature in preference to the clamp is altogether ignored, showing the general acceptance of the use of clamps as the only means of fixing the ligament.

FONCTIONNEMENT DE LA MAISON D'ACCOUCHEMENTS BAUDELOCQUE. CLINIQUE DE LA FACULTÉ. DIRIGÉE PAR LE PROFESSEUR ADOLPHE PINARD. Année 1892. DR. G. LEPAGE, Ancien Chef du Laboratoire de la Clinique, Chef de Clinique. Paris: G. Steinheil, 1893.

THIS report details the work of the Clinique Baudelocque for the year 1892. Although many of the cases were used for purposes of instruction, and a large number of students participated in the demonstrations, not a single accident resulted from infection as a result of defective asepsis. The students were also afforded an opportunity of vaccinating the newborn children and observing the course of the resulting vaccinia. During

the year, 1834 cases were delivered at the clinique. Among this number there were eight deaths, including three from puerperal septicemia. Forty-two additional cases entered the gynecologic service. The forceps was applied in 76 cases. Basiotripsy was performed in 9 cases; craniotomy in but 1. Cervical embryotomy was performed in 4 cases; spinal embryotomy in 1. Premature labor was induced in 3 primiparæ having normal pelves and in 8 women (4 primiparæ and 4 multiparæ) with deformed pelves. Symphysiotomy was performed in 13 cases; all of the mothers were saved and 10 of the children. Ischio-pubiotomy was performed in 1 case. Version was performed in 10 cases. There was but 1 case of ectopic pregnancy, which was brought to a successful issue by celiotomy. In 34 cases the placenta was removed by means of the hand. Ten primiparæ and 10 multiparæ were delivered of twins. Seventeen of the children presented malformations, or deformities, or monstrosities. There were 21 cases of purulent ophthalmia.

History of the Life of D. Hayes Agnew, M.D., LL.D. By J. Howe Adams, M.D. With fourteen full-page portraits and other illustrations. 8vo, pp. 376. Philadelphia: The F. A. Davis Co., 1893.

Dr. Adams writes in an entertaining style, and his text is, on the whole, interesting. The skill and energy of Dr. Agnew and the lovable character that won him so many friends are well set forth. Among minor errors of incidental gossip is the statement that the Philadelphia Polyclinic grew out of the Philadelphia School of Anatomy or took its first faculty therefrom. Dr. Roberts and Dr. Leffmann, of the faculty of the School of Anatomy, were members of the first faculty of the Polyclinic. Others who had been connected with that school have, from time to time, likewise become connected with the Polyclinic and, under Dr. Steinbach, the operative-surgery classes of the Polyclinic have been instructed at the rooms of the Philadelphia School of Anatomy. There is thus a connection between the two institutions, but not the one Dr. Adams imagines. This correction is made as a matter of local medical history.

Transactions of the Fourteenth Annual Meeting of the American Laryngological Association, held in the City of Boston, June 20, 21, and 22, 1892. New York: D. Appleton & Co., 1893.

This volume of *The Transactions of the American Laryngological Association* is of the same high standard as its predecessors. The articles show care in preparation. Some of the cases reported are unique, and almost all are interesting. The views advanced are largely based on actual clinical work, and this always carries weight. The volume does much credit to the Association.

Appendicitis and Perityphlitis. By Charles Talamon. Detroit: G. S. Davis.

In this new addition to the Physician's Leisure Library, we find a most able and brilliant discussion of a malady that at present claims a large share of professional attention.

We are acquainted with no treatise on this subject that so clearly describes the lesions and their causes, that sets forth the diagnosis and symptoms in so lucid a manner, or that deals with opposing views with a fairness so temperate and judicial.

It is a book worthy of critical review and one that will prove of value to every practitioner of medicine and surgery. It is especially gratifying to observe the credit that this distinguished Frenchman accords to American observers.

Handbook of Massage. By Emil Kleen, M.D., Ph.D. Authorized Translation from the Swedish by Edward Mussey Hartwell, M.D., Ph.D. 8vo, pp. 316. Philadelphia: P. Blakiston, Son & Co., 1892.

The introduction to the American edition of Kleen's work, written by Dr. Weir Mitchell, characterizes it as a "calmly scientific statement of the uses and effects of massage." We cordially indorse this high commendation. In addition, its fulness, the clearness of its descriptions, and the evident sincere truthfulness of the author give the book an almost inestimable value. Wearied of extravaganza on the one hand, and on the other of exasperatingly incomplete manuals, the physician who has almost despaired of finding a comprehensive but not tiresome presentation of the important subject of mechanical therapy will find in this book the desideratum so long sought. Anything more must come from personal experience. The book is well indexed.

The Modern Antipyretics: Their Action in Health and Disease. By Isaac Ott, M.D. Second edition, revised and enlarged. 8vo, pp. 125. Easton, Pa.: E. D. Vogel, 1892.

The second edition of Dr. Ott's useful little manual is enlarged by a more elaborate study of heat-regulation, incorporating the author's researches published in various journals, and the practical deductions are set forth more at length. Some new agents are considered. We can only repeat our former commendation of the author's spirit, methods, and work.

CORRESPONDENCE.

PRECOCIOUS PREGNANCY AND OTHER UNUSUAL CONDITIONS.

To the Editor of The Medical News,

Sir: Noticing the report of a case of precocious pregnancy in a recent number of The News, I concluded that the following would be of equal interest, and even more so, as the dates are of an earlier age. When practising in Liverpool I attended a girl who was delivered *seven days* after her *thirteenth* birthday. I have only her mother's assertion of the fact, but judging from general appearance I had every reason to believe her correct. The growth on the mons Veneris was exceedingly slight, scattered and of a light color. The labor was very tedious, and though the girl might have been delivered without instrumental aid, still I thought it advisable to assist her and thus prevent after-exhaustion and possible flooding

The following, though not relating to pregnancy, may also be of interest:

A very tall, well-developed girl was brought by her mother to my surgery. I concluded that her age could not be under nineteen, and was astonished to learn that she was but *eleven*, and that menstruation had commenced between seven and eight years of age. The girl's brother, whom I subsequently saw, was in height about five feet eleven inches, well developed and muscular and with no small amount of whiskers. His age was *thirteen*. He had been working in a foundry or iron-works for about twelve months.

I have seen a short, under-sized girl, or in appearance a woman, with breasts full, voice strong and not childish, and whose age was nine, and whose mother stated that menstruation had been established, and regularly, for about eighteen months.

The last and most extraordinary case was that of a lady, aged eighty, with whom menstruation commenced (if I remember correctly) between sixteen and seventeen. She had known no menopause, and, with the exception of the periods of gestation and lactation, had menstruated regularly to the time of her death. All her daughters, five in number, had ceased menstruating years previously.

I gave it as my opinion that on its cessation death would result, which proved correct toward the approach of her eighty-second year. The old lady was a widow. A very interesting point in her case would be this: Had she been married in her advanced age, could pregnancy have resulted?

Your obedient servant,

LOGAN RUSSELL, I.P., F.R.C.S.,
Surgeon-Captain, Garrison Artillery Militia.

GOVERNMENT PARK, ST. CATHERINE, JAMAICA.

SPONTANEOUS RUPTURE OF THE SYMPHYSIS PUBIS DURING LABOR.

To the Editor of THE MEDICAL NEWS,

SIR: THE NEWS, July 15th (p. 73), contains a report of the spontaneous rupture of the symphysis pubis during the application of forceps. I have seen the same occurrence without the use of the forceps. Last winter I was called to see a robust woman two or three weeks after her confinement, with a swelling in the pubic region. The forceps had not been used, although she stated that she had been torn apart. Evidently the attending physician had his fingers in the vagina when the rupture occurred. I incised the abscess, which I found, and introduced my finger between the separated ends of the symphysis. The cartilage seemed destroyed. A few days of drainage and a band around the hips sufficed to effect a cure. About six weeks later the woman was up and around. Whence came the infection? The woman's pelvis was somewhat narrow, as well as I remember; in two previous confinements in which I attended her, the fetuses were expelled only after the most formidable pains, and in one I applied the forceps.

Very respectfully,

M. HARTWIG.

BUFFALO, N. Y.

Veit has retired from the Chair of Gynecology at Bonn. Fritsch, of Breslau, is in contemplation as his successor.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-first Annual Meeting, held at Newcastle-upon-Tyne, August 1, 2, 3, and 4, 1893.

(Continued from page 195.)

FOURTH DAY—AUGUST 4TH.

DR. C. J. CULLINGWORTH delivered the Address in Obstetrics and Gynecology, which was entitled, "On Pelvic Peritonitis in the Female, and the Pathologic Importance of the Fallopian Tubes in Connection Therewith."

He pointed out some of the advances that have been recently made in our knowledge of pelvic inflammations, and more especially pelvic peritonitis. The subject includes the most common and, from their far-reaching effects upon the sufferer's health and usefulness, probably the most important of all the diseases of women. It almost equally concerns the obstetrician and the gynecologist, and has now been delivered, or nearly so, from the bondage of theory and tradition and the authority of great names, and may at length be studied in the light of well-ascertained facts.

Allusion was made to the work and writings of M. Bernutz, one of the greatest gynecologists of the century. At the time when Bernutz published his clinical memoirs it was the current belief that the hard swellings felt above the vaginal roof on one or both sides of the uterus in cases of pelvic inflammation were invariably due to inflammatory exudation in the connective tissue at the base of the broad ligament, or between its layers. Various names were given to these exudations, but whether they were described as pelvic cellulitis, or parametritis, or peri-uterine phlegmon, there was practically no difference of opinion as to their seat. For some time Bernutz himself participated in the common belief. The fatal termination, however, of two cases under his own care served effectually to change his views, and enabled him "to prove incontestably that the peri-uterine tumor, which during life presented all the symptoms of the so-called peri-uterine phlegmon, was not situate in the cellular tissue at all. In the necropsies in question the tumor, which even after death presented all of the usual signs, was seen to be formed by the pelvic viscera matted together by peritoneal adhesion." One of the cases was that of a young woman of eighteen, who had led an irregular life for twelve months, and who on the eighth day of an attack of gonorrhea was suddenly seized with severe pain of progressive intensity in the lower part of the body. In addition to the usual signs of acute gonorrhea there was discovered on examination a resisting body above the vaginal roof, extending all round the cervix except on its right side. Pressure on the tumor caused great pain. Rest, and the application of leeches to the left iliac region, gave some relief, but the swelling remained the same, and a few days later the pains returned. After some weeks the patient had an attack of jaundice, and then pleurisy with effusion—first serous, and, after the first tapping, purulent. She died after three months. On *post-mortem* examination the bladder, uterus, broad ligaments, and sigmoid flexure were all found matted together by old adhesions.

There was no cavity on the left side of the pelvis, the broad ligament being united to both bladder and rectum. On separating these adhesions an intra-peritoneal abscess was opened. The uterus was bound posteriorly to the rectum. The Fallopian tubes were highly congested. The right one contained two collections of pus, one at the fimbriated extremity, which was dilated and firmly adherent to the ovary. The left tube contained no pus, but was impermeable. The ovaries were both healthy. The cellular tissue of the broad ligaments and uterus were perfectly healthy. The supposed phlegmon did not exist.

In 1862 Bernutz, in conjunction with his friend, M. Goupil, published in a collected form a marvellous series of clinical memoirs, which constitute by far the most important contribution ever made to the literature of gynecology.

The conclusions at which Bernutz arrived as a result of his researches have been summarized by himself as follows: (1) That inflammation of the pelvic peritoneum is a disease very commonly met with; (2) that the tumor found after death in cases of pelvic peritonitis is formed by various intra-pelvic viscera being matted together as a consequence of the inflammation; and (3) that inflammation of the pelvic serous membrane is always symptomatic, and that it is generally symptomatic of inflammation of the ovaries or Fallopian tubes.

It might be thought that views so clearly expressed and supported by such incontrovertible evidence must needs have met at once with general acceptance, and become part of the common stock of professional knowledge; but they did nothing of the kind. For twenty years the old views continued to be generally taught, and even yet they form the basis of much of the current teaching and practice in regard to pelvic inflammations.

The new views might possibly have attracted more attention had it been made to appear that they had any important bearing upon treatment. Many years, however, were destined to elapse before the discoveries of Bernutz found a practical application, and even then it was not, in the first instance, as a direct result of those discoveries, but as an outcome of that surgical enterprise which, just as it had opened new avenues of knowledge and new possibilities of relief and cure by operative treatment in the case of the kidney, is doing the same for other organs of the body, and notably for those which are chiefly concerned in the production of pelvic peritonitis.

In the year 1872 the operation for the artificial induction of the menopause, by the removal of the healthy Fallopian tubes and ovaries, was carried out by three operators of different nationalities at dates so closely following one another and yet at places so remote that it was practically impossible for there to have been any sort of concerted action. On July 27th, Hegar performed the operation at Freiburg in a case of ovarian pain and menorrhagia. Five days later Lawson Tait operated at Birmingham on a case of uterine myoma with excessive hemorrhage; and within three weeks of Hegar's operation, a highly respected American gynecologist, Dr. Robert Battey, of Rome, Georgia, performed a similar operation on a patient with hystero-epilepsy and amenorrhea. At the instance of Dr. Marion Sims, the operation has been named after his compatriot, Dr. Battey, who appears to have conceived the idea of the operation seven years before he had an opportunity of carrying it out, and who certainly can claim the credit of having been the first to publish his case and to bring the whole subject before his professional brethren for discussion.

In the course of two or three years the number both of operations and operators began rapidly to multiply, so that at the International Medical Congress held in London in 1881 Battey showed a table of 193 complete and 25 partial operations. The general death-rate of these was 18 per cent., but individual operators were beginning to show a greatly diminished mortality. Tait, for example, reported 26 consecutive cases with but a single death, and Savage reported an equal number with no death at all. With such results as these it was to be expected that the scope of the operation would soon be widened, and instead of being limited to the removal of the normal organs, would be extended to cases in which the uterine appendages were themselves the seat of the disease. And this is precisely what took place. In the years 1879 and 1880 Hegar, in Germany, and Lawson Tait, in England, operated on several patients for the removal of inflamed ovaries and tubes, and then it was that the accuracy of the observations of Bernutz came to be fully recognized, and his apparently barren discoveries to bear their legitimate fruit. The knowledge at which he had arrived by *post-mortem* investigation was now arrived at in a different, but at least equally conclusive, way, by actual inspection and touch during life.

In the vast majority of cases in which the mobility of the uterus is more or less impaired, and in which hard, irregular, fixed swellings can be felt above one or above both lateral fornices of the vagina, and often extending into Douglas's pouch, no evidence of cellulitis is to be found, and when it does exist it is clearly secondary to the salpingitis and peritonitis which constitute the principal lesions present. Inflammatory exudation in the cellular tissue of the broad ligament or elsewhere, sufficient to form a distinct tumor recognizable as such by bimanual examination, is exceptional. In some cases of chronic suppurative inflammation of the uterine appendages, the broad ligaments are the seat of a certain amount of thickening from inflammatory exudation, but this obtains only in the neighborhood of the suppurative disease, and the thickening seldom exceeds one-eighth of an inch, and even in extreme cases rarely exceeds half an inch. The usual state of things disclosed on opening the abdomen in these cases is as follows: The contents of the pelvis are generally concealed from view by the great omentum, which has been drawn down so as to cover them in anteriorly, and has contracted adhesions to the peritoneum as it becomes reflected upon the anterior abdominal wall, as well as upon the uterus and other pelvic viscera. Along with this screen, as it were, of omentum it is not unusual to find coils of adherent small intestine. On separating and drawing aside this screen, one side, or it may be the whole, of the posterior part of the true pelvis is seen to be occupied by what appears to be an indistinguishable mass of matted viscera. The uterus itself is sometimes implicated in the mass, but in other cases its upper part at least is free. Tracing the Fallopian tube outward from the uterine

cornu on the side of the disease, it is often found to be normal in size for the first half-inch or so, and then to become involved in the adherent mass. This mass, on being separated and brought into view, is invariably found to consist of the uterine appendages more or less altered by inflammation. There is always salpingitis, and the inflamed and thickened tube usually enfolds the ovary. In a large number of cases the ovary itself is normal, except that it is universally adherent. Whenever the lateral swelling is so large as to push the uterus to the opposite side, this condition of the ovary may be suspected. In many cases the cysts in the ovary are found to be in a state of suppuration, their contents having presumably become infected from the inflamed and suppurating Fallopian tubes. Primary ovaritis, either acute or chronic, is (apart from tuberculous disease) extremely rare.

With regard to the tubes, the first point to be noted is that the evidences of peritoneal inflammation are always most marked in the neighborhood of the fimbriated end, showing clearly that the pelvic peritonitis has originated by direct extension from the mouth of the inflamed tube or by the escape of morbid secretions therefrom. When the secretion from the inflamed tube is chiefly mucous in character, with only a slight intermixture of pus-corpuscles, the intensity of the inflammation around the abdominal ostium is shown by the extreme density of the adhesions at that spot, and nothing more. When the secretion, on the other hand, is wholly purulent, either an intra-peritoneal abscess is found, encysted among adhesions, and fed by the purulent discharge issuing from the open mouth of the suppurating tube, or the pus, accumulating in the occluded tube, distends it, sometimes uniformly but more often irregularly, forming a series of loculi or pouches full of pus here and there along the tube, in either case constituting the condition known as pyosalpinx.

The changes in the walls of the tube are as follows: In acute cases the mucuous membrane, including the projecting longitudinal folds, is found highly congested and swollen and covered with purulent or muco-purulent secretion; in chronic cases the condition varies according to whether the inflammatory secretions are pent up within the tube or have made their escape from the open fimbriated end. In the former case the mucous membrane is either distinctly ulcerated or covered with granulation-tissue; in the latter, having got rid of its secretions, it is often found to have resumed more or less completely its normal appearance, except in the neighborhood of the adherent abdominal ostium, where it is frequently intensely congested and edematous. The most striking change in chronically inflamed tubes is due to the extension of the inflammation to the middle or muscular coat, which becomes greatly thickened and indurated from inflammatory exudation amongst the connective-tissue elements of the muscular layer, causing irregular separation of the muscle fibers and producing a general thickening of the tube-wall, which often measures from one-eighth to half an inch in thickness. The enlargement of the tube is not only manifested in an increase in its width and circumference, but frequently, also, in an increase in its length; and as this increase in length takes place within a confined space, it frequently results in the tube becoming doubled and folded upon itself, forming an intricate series of convolutions. Sometimes the convolutions take a sharp turn, forming knuckles on the external aspect, and shutting off by the suddenness of the bend one portion of the canal from the other.

In advanced cases further changes may take place; the pus-containing tube becoming adherent to a cystic ovary, its wall may ulcerate and perforation occur, permitting the escape of the purulent contents of the tube into the interior of the cyst and the formation of tubo-ovarian abscess. The result of such an accident is a sudden and most violent attack of pelvic peritonitis, placing the life of the patient in eminent peril. It must not, however, be supposed, whenever an inflamed and purulent tube is found suddenly to lead into a large abscess-cavity, giving an appearance that has been happily compared to that of a retort, that the condition is necessarily one of tubo-ovarian abscess.

When the salpingitis is unilateral, it is not at all unusual to find that the peritonitis spreading from its place of origin, the fimbriated end of the inflamed tube, has passed over to the other side of the pelvis, involving the healthy uterine appendages of that side in a mass of adhesions. Under such circumstances closure of the abdominal ostium of the healthy tube is likely to occur, and to be followed by the development of a hydrosalpinx, which, though then simply an incident in the course of an attack of pelvic peritonitis, may in its turn itself become a source of suffering and ill-health. Hematosalpinx, as a complication of salpingitis, is much more rare. In the great majority of cases hemorrhages within the tube and hematoceles of tubal origin are the consequence of tubal gestation, but now and then they occur as incidents in the course of the inflammatory processes just described, and quite independently of gestation.

The Fallopian tube is exposed to constant risk of infection, owing to the direct continuity of its lining membrane with that of the uterus and vagina, so that it is almost a miracle if it escapes in any case of acute infective endometritis, whether septic or gonorrheal. But there is the widest possible difference between the danger of an acute endometritis and that of an acute endosalpingitis. In the former the patency of the cervical canal provides a natural outlet for the morbid secretions; in the latter there is no such natural outlet. The uterine end of the Fallopian tube has, even under normal circumstances, a lumen only just large enough to admit a fine bristle. It will, therefore, be readily understood that it only requires a very slight amount of swelling of the mucous membrane, such as is probably inseparable from the mildest inflammatory attack, to block up that end completely. Hence, as an outlet for inflammatory secretions, the uterine orifice may practically be regarded as non-existent. The position of matters, therefore, is that either there is no outlet at all for the morbid secretions, owing to the closure of one orifice by the swollen mucous membrane and the closure of the other by adhesions, or the only outlet is through the abdominal ostium into the peritoneal cavity. It is this fact of the absence of a safe outlet for inflammatory products that makes an attack of suppurative salpingitis so much more serious a matter than an equally severe attack of suppurative endometritis, and that invests the inflammatory affections of the Fallopian tube generally with such an exceptional and grave importance.

It is not only in pelvic pathology, however, that additions to our knowledge have recently been made; our powers of diagnosis have been enlarged.

In order to make a satisfactory bimanual examination in a suspected case of pelvic inflammation it is essential that the patient be in the dorsal position, with the knees flexed and separated, the head supported on a single pillow, and the shoulders not raised, as is generally recommended, but lying flat on the couch or bed. To avoid strain (and no examination can ever be satisfactory in which the posture of the examiner involves the least strain), the examiner should stand or sit directly in front of the patient.

In considering the value of operations undertaken for the removal of the uterine appendages as a mode of treatment, it is desirable, in the first instance, to make a clear distinction between the operation for the removal of the uterine appendages when there is no obvious lesion of either tube or ovary, and the same operation when those parts are the seat of manifest disease. The scope of Battey's operation—that is, the operation for the artificial induction of the menopause, never very wide, has become narrower and narrower as experience has increased, and is now practically restricted to the treatment of certain cases of uterine myoma. As a means of relieving neurotic conditions, it is so terribly open to abuse, it raises so many difficult questions that are better left undisturbed, and it has proved so uncertain and disappointing in its results, even when legitimately applied, that it is now thoroughly and properly discredited. At the same time it must never be forgotten that it is to the men who first conceived and carried out Battey's operation that we owe not only a method of dealing with uterine myomata that has saved many a life, but also the further development of pelvic surgery, which is one of the greatest triumphs of modern gynecology, as illustrated by the operation for the removal of the uterine appendages when they are the seat of serious disease.

It was finally pointed out that not every case of inflamed Fallopian tubes should be operated upon. On the contrary, most of them recover without operation. But there is a large residuum of cases—most of them chronic, some few acute—in which nothing but an operation can save life. And there is a still larger number of cases in which a timely operation rescues the patient from years of misery, incapacity, and chronic invalidism. Every case has to be considered individually; no rules can be laid down which shall be of universal applicability. The woman who has her bread to earn, or who is the busy wife of a working-man, cannot afford the luxury of an illness extending over several years, and an operation would be justifiable in her case when it would not be in the case of her more well-to-do sister. The operation is, in short, not a universal panacea, but an invaluable addition to our resources, which, when it is adopted in suitable cases, with a due sense of responsibility, and after full explanation to the patient and her friends, both of the immediate risk and the ultimate physiologic results, is capable of achieving triumphs as remarkable as any operation in surgery.

Cholera in Berlin.—It is announced that on August 15th, three Polish laborers died of cholera in the eastern quarter of the city of Berlin.

THE SURGICAL TREATMENT OF EXOPHTHALMIC GOITER.[1]

BY ALBERT H. FREIBERG, M.D.,
OF CINCINNATI, OHIO.

THE treatment of Graves' disease constitutes one of the unsatisfactory chapters in therapeutics. One does not have to look far into the literature of the subject to find conclusions widely different. A. praises the virtues of galvanism; B. vaunts the efficacy of digitalis; while C. may be found extolling the properties of belladonna, aconite, veratrum viride, or duboisin. It is a fact that no one claims to cure very many cases. In studying the treatment, one soon concludes that, in the majority of cases, staying the progress of the disease for a variable length of time is all that is to be expected. This is scarcely to be wondered at, in consideration of the fact that we are in the dark as to the nature of the disease. We are not only ignorant of its seat, but we do not even know whether it is organic or functional. What we do know is, principally, that a certain symptom-complex occurs with sufficient frequency to characterize it as a definite disease, and careful clinical study in late years has made our task even more difficult in having recognized the occurrence of incompletely developed forms, the interpretation of which is by no means always easy.

The triad of symptoms originally described as characteristic of Graves' disease, tachycardia with subjective sensation of palpitation, a vascular swelling of the thyroid gland, and exophthalmos, has been added to by the observation of various symptoms on the part of the eye and the general nervous system. Under the latter head may be mentioned tremor, hyperidrosis, subjective sensations of heat, vertigo, nausea, vomiting, and insomnia; a marked diminution of the resistance of the skin to the electric current is also almost constantly found. In the eye, Graefe's symptom, a failure of the upper lid to follow the downward movements of the globe, holds the most prominent position as a diagnostic point, excepting, of course, the exophthalmos; an almost entire absence of the involuntary wink was also described by Stellwag, and this symptom bears his name. It was the result of Marie's[2] exhaustive study of the subject, however, to show that cases occur in which any of these symptoms may be absent; that the combination of only one of the cardinal symptoms with some of the other nervous manifestations may be all that we have with which to make a diagnosis. The disease is always harassing to the patient, if it be at all strongly marked, and, if it progress, may lead to the development of a decided cachexia and to a lethal ending.

This is neither the time nor place for an exhaustive discussion of the pathology and causation of exophthalmic goiter, but a short consideration of the principal theories may be of interest, and will certainly aid us in judging the results of the treatment. Following Gauthier's classification, the theories proposed for the explanation of exophthalmic goiter may be placed in three divisions:

1. *The cardio-vascular theories*, which locate the seat of the disease in the heart itself, the vessels, and the blood.

2. *The mechanical theories*, which connect the symptoms with compression of vessels or nerves in the neck by the primarily hypertrophied thyroid.

3. *The nervous theories*, which attribute the disease to disturbances in the pneumogastric, in the sympathetic itself, or in the central nervous system proper.

The cardio-vascular theories we can put aside without any further discussion, as they have, at the present day, few or no supporters. Not so, however, the mechanical theories. These concern us deeply, for upon them a number of surgical authorities base their procedures in the attempt to establish a rational treatment. On the strength of these has surgery again invaded a new territory, where previously her interference was not thought of. The mechanical theories attribute the origin of the symptoms to pressure on the organs of the neck by the goiter itself. Some consider the vessels as suffering chiefly from this pressure; others the sympathetic or vagus; and still others believe the symptoms to result from pressure on nerves and vessels together. In support of the mechanical theory, its advocates pointed to the clinical observation of cases in which the onset of nervous symptoms coincided with the growth of a previously existing goiter of whatever character, and in which at the same time other evidence of pressure was manifest by the inter-

[1] Read before the Association of American Physicians in Berlin.

[2] Marie: Contribution à l'étude et au diagnostic des formes frustes de la maladie de Basedow.—Paris, aux Bureaux du Progrès Med. 1886.

currence of dyspnea or dysphagia, for instance. However effectually the clinical testimony of the opponents of the mechanical theory confuted it as applying to Graves' disease in general, it could not be denied that the theory seemed applicable to a certain number of cases. Just as unlikely as it was that exophthalmos and tachycardia existing for months or years before the development of a goiter could be caused by pressure from this goiter, just so likely did it seem, in the other class of cases, that the increase of size in the thyroid gland was directly responsible for the nervous symptoms following it. Especially so was this the case when other differences in the two classes of cases seemed to be apparent. Thus, as early as 1869, Eulenburg[1] attempted the differentiation of "true morbus Basedowii" from struma causing irritation of the sympathetic. As characteristic of the latter condition, he gives symptoms of *irritation* on the part of the pupil and vasomotor nerves, while in "true Basedow's disease" pupillary symptoms are entirely absent, and paralytic symptoms on the part of the vasomotor nerves of the head are manifest. He likewise mentions stenocardial attacks and psychic symptoms as belonging to true morbus Basedowii, and not to the other.

Gauthier[2] is of the same opinion regarding these two forms. He speaks of a "surgical Basedow's disease," caused by the primary hypertrophy of the thyroid, and of true Basedow's disease. He gives the clinical history of a case which, in this connection, is very interesting. A female patient, aged sixty, presented herself with a cystic goiter of thirty years' standing. "She had all the symptoms of Basedow's disease." The cyst was emptied by puncture, and injected with iodin, and the patient was discharged, cured of her symptoms. Seven years afterward the gland enlarged anew, and the patient again presented the symptoms of Basedow. Her death prevented a second operation. The clinical course of this case certainly renders it probable that the nervous symptoms were due to the size of the tumor. Gauthier cites a case of MacNaughton Jones's, and one of Ollier's of similar character. Dubrueil[3] also reports a case in a young man of twenty-two, who had a goiter of the right side, the size of an apple, and of two years' standing. The tumor fluctuated, and was absolutely without pulsation; slight bilateral exophthalmos was present, and the pupils were dilated, "especially the right one;" the pulse was 120; the heart's action was abnormally strong, and a systolic blowing could be heard at the apex. About 200 g. of a brownish fluid were withdrawn from the cyst by puncture; but as it refilled in a few days it was enucleated. The man was discharged "cured," after several weeks, with a pulse of 80. It would seem that this case should be classed under the heading "surgical," if such a term be justifiable, and I think that, with our present imperfect knowledge of the subject, it is so.

However, the mechanical theory is applicable to a limited number of cases only, and for the explanation of the far greater number recourse has been had to the nervous theories, although they are almost entirely hypothetic or inferential. The result of the surgeon's interference in cases of true Graves' disease, however much the patients may have been benefited, has been only to add to the mystery at present enveloping the pathology of the disease. I have thought it advisable therefore to search in the literature for enlightenment, to ascertain what has been done, and what conclusions may be drawn on this subject.

As pioneers in subjecting exophthalmic goiter to surgical procedure we must consider Jones, Gauthier, Ollier, and Tillaux. In the cases operated upon by Jones and Ollier, however, the indications seem to have been rather the symptoms caused by the size of the tumor than the nervous manifestations. This, indeed, would also appear to have been the case with Tillaux, although in his report he discusses the case as one of Basedow's disease. Rehn seems to have been the first to operate in a case of Graves' disease, although the report renders it likely that the large struma was not the primary trouble. In the majority of cases reported, both before and after his, the size of the tumor would have been sufficient indication for the performance of the operation. It is upon those cases, however, in which the thyroid enlargement plays a lesser rôle, that we must depend in appraising the value of operation in true Graves' disease; not that a large goiter is a bar to the diagnosis, but because the more typical cases are those in which the thyroid tumor does not assume very large proportions.

It is by no means easy in passing on the cases reported in the literature to distinguish between true Graves' disease and symptomatic or "surgical" exophthalmic goiter, and this is highly desirable. Aside from the fact that the clinical identity of these two conditions is by no means positive, and that this classification is to a very large degree arbitrary; apart from the fact that it is impossible in many cases to differentiate, clinically, the "surgical" from the "true" form of Graves' disease, the reports in very many or most of the cases are so imperfect that it is difficult to estimate their value in attempting to arrive at conclusions. The importance of properly interpreting cases reported is manifest, for upon this largely rests the position in surgery that operation for exoph-

thalmic goiter is to hold. Furthermore, by the results of previous operations must we form the indications for surgical procedure, if we believe this to be justifiable.

Assuming, then, that we have good reports before us, there still remain very considerable difficulties in our way. In the first place, the nature of the struma itself has given rise to doubt. Trendelenburg, for instance, in reviewing a case reported by Tillaux, takes exception to the diagnosis "Basedow's disease," because of the absence of exophthalmos, and because the extirpated struma contained a cyst filled with blood. Neither of these circumstances can warrant a denial of the diagnosis, though we confess that they both render it somewhat doubtful. We are willing nowadays to diagnosticate Graves' disease when the triad of symptoms is not typically present; we are even taught to diagnosticate it, though two of them be absent. On the other hand, we must recognize the fact that the struma may undergo hyperplastic and degenerative changes in typical cases of Graves' disease.

Interesting in this connection are the somewhat remarkable conclusions of Schrang.[1] This author reports that of 3304 cases of ordinary goiter examined by him, during life and post mortem, 344 of them, 10 per cent., had heart-trouble of one kind or another, without valvular lesion; a considerable number more had valvular lesions. A large number of these patients consulted the physician primarily on account of palpitation of the heart, and so convinced is Schrang of the relation between goiter and heart-disease, that he declares the cause of death in goitrous patients, as a usual thing, to be heart-failure, whether from simple dilatation, degenerative changes, or actual valvular lesions. As the result of his long experience, he believes that certain forms of goiter can cause "cardiac degeneration;" and, what is still more remarkable, that hyperactivity and hypertrophy of the heart can produce a goiter. In what manner this can be brought about he does not clearly show, relying on the statistics mentioned for his statement. This is of importance to us, in so far as it must make us very cautious, in this investigation, about accepting the diagnosis, "true Graves' disease," in any case in which the three cardinal symptoms are not present, and in which the clinical history given is not sufficiently complete to remove all doubt as to the nature of the case. Thus, in this very case of Tillaux's, Trendelenburg is perfectly justified in his doubt, as exophthalmos was absent, and the tumor was large enough to cause dyspnea, and was of cystic character.

In attempting to conclude whether or not any cases reported as cured by operation were cases of "true Graves' disease," I believe the clinical history to be the safest criterion; that is to say, if exophthalmos and tachycardia were present before the development of the goiter in a given case, it certainly seems evident that the goiter, *by virtue of its size*, could not be considered their cause.

Let us now turn to the literature, and endeavor to select therefrom all cases of exophthalmic goiter that were subjected to surgical interference, whether this consisted in extirpation with the knife or in the older methods, such as the use of the seton and caustic. The total number of cases found is forty-one; of these, extirpation of the goiter was practised in thirty-three; and of these, partial extirpation in twenty-one, total extirpation in one; and in the remaining eleven cases the exact nature of the operation is not given. Two of the patients operated upon died. The mortality of these extirpations is, therefore, about 6 per cent. Three cases were treated by ligature of the thyroid arteries, and five by the seton, caustic, or simple puncture; all of these recovered. Twenty-five were reported cured of all symptoms; eleven were improved; three were unimproved; and in fact in one of these three cases the exophthalmos is said to have become more pronounced after the operation. Of the forty-one cases reported, twenty-five are said to have been cured, but only in fifteen does the report cover a period of more than six months from the time of operation; several are reported after intervals of from six weeks to four months. According to the reports of the various authors, more cases are characterized as "cured" than my summary will show. In several cases the author, after reporting his case "well," goes on to tell how the "exophthalmos was very much less," the "struma almost disappeared," "the pulse now perfectly regular, and beating 80–90 a minute," and so on. As long as any of the cardinal symptoms remain after operation the case cannot be said to have been cured; amelioration of the patient's condition can in such a case justify only the predicate "improved."

For the sake of a better appreciation of the cases, I have tried to divide them into three classes from the histories given. I have classed as "surgical" those cases in which the nervous symptoms seemed directly dependent upon the size and growth of the goiter. Not only does Eulenburg mention this class of cases, but Gowers[1] also says that "a large struma, of endemic origin, often presses on the sympathetic, and perhaps on the vagus, and causes palpitation and exophthalmos." I have considered as instances of "true Graves' disease" only such cases in which

the struma was not the first of the classic triad to appear, and, with one exception, those in which goiter, exophthalmos, and tachycardia were all present. As "doubtful" I have classed the remaining cases when the history reported would not warrant my including them even under such arbitrary heads as the others. Classed as cases of "true Graves' disease," there were then eleven, of which seven were reported cured; and as cases of "surgical Graves' disease," were ten, of which nine were cured; and as "doubtful cases," were twenty, of which nine were cured. If we assume the doubtful cases to have been instances of true Graves' disease, we have thirty-one cases, of which sixteen were cured, that is about 50 per cent.

The duration of the cure must greatly interest us. Unfortunately, there is nothing mentioned of this in many of the reports. Only once is there mention of recurrence, and this was in the case reported by Gauthier, already mentioned. This was probably not a case of "true Graves' disease." Three cases are reported as being well five years or more after operation, two after three years, two after two years, three after one and a-half years, one after seven months, and one after six months.

From the study of these cases, it seems evident to me that whether the term "surgical" be appropriate or not, in the development of large tumors of the thyroid gland of whatever nature there may arise a symptom-complex very similar to, if not identical with, true Graves' disease. In two of the cases the goiter was reported as sarcomatous, in five as cystic, and in several as very vascular; in the greater number of cases, all description of the nature of the goiter is omitted.

I certainly believe that cases of true Graves' disease have been greatly relieved of their symptoms by operation; perhaps some of them have been cured.[1] It seems to me unwarrantable to draw positive conclusions as to the pathology of Graves' disease from the results of these operations alone; in fact, it seems almost as difficult to do so in those cases of the so-called "surgical" form. Josipovici,[2] Weidemann,[3] and others conclude that, inasmuch as the extirpation of one-half of the tumor was followed by disappearance of the symptoms, the symptoms were due to pressure from it. How frequently does the surgeon observe goiters of large size which have exerted such pressure on the organs of the neck that the functions of breathing and swallowing have been almost abolished, and yet the sympathetic has escaped pressure in some wonderful way; these cases present no symptoms of Graves' disease. The symptom that, according to Eulenburg and Gowers, speaks strongly in favor of pressure on the sympathetic, pupillary dilatation, is found reported three times only in our forty-one cases; yet a considerable number of the goiters are reported as of large size. How equally inconsistent with the pressure-theory are those cases presenting all of the symptoms of Graves' disease in a marked degree, but in which the struma was by no means the first of the

[1] During the discussion of this paper it was suggested that the test of the cutaneous resistance to the electric current might be a good test of the completeness of the cure after operation; this has, to my knowledge, been tried by no one as yet.

[2] Josipovici: Zur Therapie d. Morb. Based. Dissert., Berl., 1887.

[3] Weidemann: Kropfextirp. im Augusta Hosp. Dissert., Berl., 1886.

symptoms to appear, and even never equalled a peach in size. To bring our mystification to a climax, then, the extirpation of one-half of such a struma is followed by the disappearance of all the symptoms.

Rehn,[1] in his first publication on the subject, after reporting favorable results from four operations, suggested that the symptoms of Graves' disease may be reflex manifestations on the part of the sympathetic nerve-endings in the thyroid gland. Hack[2] afterward reported a cure of Graves' disease by nasal operation, and since this several others have recorded similar success. Hack's case was one of typical Graves' disease in a patient afflicted with chronic hypertrophic rhinitis; repeated cauterization was followed by cure of the Graves' disease, as well as the rhinitis. Hack's inference in this case is similar to Rehn's, in so far as he believed a continued irritation of the end-organs of the sympathetic in the nasal mucous membrane to underlie the nervous symptoms and the goiter.

Möbius,[3] after calling attention to the similarity between Graves' disease and myxedema, cretinism and the cachexia strumipriva, all of which are supposed to depend upon pathologic inactivity of the thyroid gland; and after noting that signs of Graves' disease may appear in the course of any goiter, and that operative measures upon the goiter often succeed in materially influencing the Graves' disease, comes to the conclusion that the principal underlying cause of Graves' disease is a morbid change in the functional activity of the thyroid gland; the cause of this morbid activity he acknowledges to be entirely unknown, but suggests its being an intoxication. Wette[4] comes to a similar conclusion, though by the much less logical reasoning that as the removal of the goiter is followed by disappearance of the nervous symptoms, the goiter must be the etiologic factor underlying the Graves' disease.

One factor, however, which occurs to me as worthy of consideration in this connection has failed being mentioned by any of these authors; I refer to the effect of the operation *per se*, aside from anything akin to suggestion. It strikes me that a certain analogy exists, in this relation, between epilepsy and Graves' disease. The fact that many cases of exophthalmic goiter seem to date directly from the occurrence of a bodily injury, mental excitement or shock, and that we have no positive proof, as yet, that the strumectomy has achieved a lasting cure in Graves' disease, greatly strengthens, for me, at least, this similarity. After considerable search in the literature I have failed to find anything referring to the effect of general surgical operations on the course of Graves' disease. Experience in this connection might be expected to aid us materially in our consideration of the subject.

Gowers[1] gives 25 per cent. as the proportion of cases of true Graves' disease cured or brought to a standstill by non-operative methods. In his last report of 250 cases of all kinds of goiter, Mocher gives a mortality from strumectomy of 1.8 per cent.; it is true that his first cases of Graves' disease (a report of which in detail I have not been able to find) were attended with a greater mortality than his other strumectomies. He expresses the conviction, however, that with our present improved methods of operating, exophthalmic goiter should be no more dangerous to operate upon than the others, and I think that the results reported since his publication bear this out. When we consider the slight danger to life from the operation, if carried out according to the most improved principles; and when we consider the favorable results thus far obtained by surgical treatment, it seems to me that in cases of true Graves' disease of such severity as to seriously harass the patient, and when the other methods have failed to arrest the progress of the disease, operative interference is indicated. In cases of the so-called "surgical" kind, or in any case in which the goiter is of sufficient size to cause stenosis of the trachea or esophagus, the indications for operation will be self-evident. However this may be, we can regard the operation for true Graves' disease, as yet, only as empirical; all the more is it important, therefore, that future cases be reported with utmost care in the details. As far as the choice of operation is concerned, I shall have little to say. The operation at present almost exclusively performed is the extirpation of one-half of the gland, usually the larger half being chosen. The superior and inferior thyroid arteries are tied as a preliminary step and the isthmus is divided between ligatures. Ligature of the thyroid arteries alone might well come up for consideration; however, three cases only have been reported, one as well, and the other two as improved. Total extirpation, practised as it was at first, is at the present day, of course, out of the question.

Although we can scarcely exclaim with the enthusiasm of a recent German author that "henceforth Basedow's disease belongs in the surgical ward," the surgeon's past work in this field has certainly merited encouragement. We shall express the hope that future experience may result in further justification of the surgical treatment, so that increase of knowledge may convert what is now an empirical procedure into one thoroughly rational.

A STUDY OF THE "ORGANIC EXTRACTS" "CEREBRINE" AND "CEREBRIN."

By G. ARCHIE STOCKWELL, M.D.,
of Detroit, Mich.

The announcement made by Dr. W. A. Hammond in an article entitled "On Organic Extracts, their Preparation and Physiological and Therapeutical Effects," which appeared in the *New York Medical Journal*, of January 28th last, was not altogether a surprise, as Constantine Paul, taking the cue from Brown-Séquard, had been pursuing a parallel train of investigation. Abstracts or reprints of the same article were published in nearly all of the medical journals in the United States and Canada; a paper of like character even found place in the *North American Review*.

Having pretty thoroughly investigated the claims of the Brown-Séquard Fluid—which so far as evidence was concerned, appeared to possess some basis of truth, but when subjected to careful and prolonged control, proved an utter failure aside from psychic influence—I had sufficient curiosity to examine into the claims of "Cerebrine" (Hammond) and, likewise, "Cerebrin" (manufactured by Parke, Davis & Co.), as both alike rest upon the same presumptions, as promulgated in the medical and general press.

Dr. Hammond's claims, which apply equally to "Cerebrin" (Parke, Davis & Co.), are as follows:[1]

"Five minims of this extract constitute a hypodermatic dose.

"The most notable effects on the human system of a single dose are as follows, though in very strong, robust, and large persons a somewhat larger dose is required, never, however, exceeding ten minims:

"1. The pulse is increased in the course of from five to ten minutes, or even less in some cases, by about twenty beats in a minute, and is rendered stronger and fuller. At the same time there is a feeling of distention in the head, the face is slightly flushed, and occasionally there is a mild frontal, vertical, or occipital headache, or all combined, lasting, however, only a few minutes.

"2. A feeling of exhilaration is experienced which endures for several hours. During this period the mind is more than usually active and more capable of effort. This condition is so well marked that if the dose is taken about bedtime wakefulness is the result.

"3. The quantity of urine excreted is increased, when other things are equal, by from eight to twelve ounces in the twenty-four hours.

"4. The expulsive force of the bladder and the peristaltic action of the intestines are notably augmented—so much so that in elderly persons in whom the bladder does not readily empty itself without considerable abdominal effort this action is no longer required, the bladder discharging itself fully and strongly, and any existing tendency to constipation disappears, and this to such an extent that fluid operations are often produced from the rapid emptying of the small intestine.

"5. A decided increase in the muscular strength and endurance is noticed at once. Thus I found in my own case, that I could 'put up' a dumb-bell weighing forty-five pounds fifteen times with the right arm and thirteen times with the left arm, while after a single dose of the extract I could lift the weight forty-five times with the right arm and thirty seven times with the left arm.

"6. In some cases in elderly persons increase in the power of vision is produced and the presbyopic condition disappears for a time.

"7. An increase in the appetite and digestive power. Thus, a person suffering from anorexia and nervous dyspepsia is relieved of these symptoms, temporarily at least, after a single dose hypodermatically administered.

"These effects are generally observed after one hypodermatic injection, and they continue for varying periods, some of them lasting for several days. The most notable effects are seen in the general lessening of the phenomena accompanying advancing years."

With the coöperation of Dr. George Suttie, and also a personal friend deeply interested in scientific matters, who is the manager of a large manufacturing establishment, I was able to secure, on three different days, twelve men for experimental purposes. These men voluntarily submitted to the ordeal, without any knowledge whatever of the medicaments employed, further than might be conveyed by the assurance that no danger would arise therefrom; they, moreover, during the interval between the hourly recording of pulse, temperature, etc., pursued their ordinary avocations, all being of the class denominated "laboring," some employed at very heavy work; many, moreover, were obliged to climb a flight of stairs to reach the room wherein the experiments were conducted.

The fluids employed in each case were: 1st. "Cerebrine" (Hammond) in original packages, as obtained from the Columbia Chemical Co.; 2d. "Cerebrin" (Parke, Davis & Co.) in original packages; 3d. A mixture of my own, composed of 38 parts of borax, 42 parts of glycerin, and 40 parts of water.

One dozen of Hicks' thermometers with Kew certificates were obtained, and these, moreover, specially rated preparatory to experimentation, and the ratings carefully considered and verified after each individual test.

A new hypodermatic syringe was set apart for each fluid, and long before the experiments, and during the same, kept constantly immersed in absolute alcohol.

The three fluids had very nearly the same specific gravity, and the same general appearance.

Experiment No. 1, Table 1.—Dose of each fluid employed, five minims, hypodermatically.

Four men numbered respectively 1, 3, 10, and 11, and aged twenty-three, thirty-seven, thirty-five, and twenty-six years, all receiving "Cerebrine" (Hammond).

At 7 A.M., prior to receiving injection, No. 1's respiration was 17; temperature, 98.5°; pulse, 86. At 8 A.M., forty-five minutes after injection, tem-

[1] New York Medical Journal, January 28, 1893.

perature, 99°; pulse, 76. At 1 P.M., respiration, 15,; temperature, 98.6°; pulse, 76. At 7 P.M., respiration, 14; temperature, 98.5°; pulse, 64. Averages for the day, respiration, 15.33; temperature, 98.554°; pulse, 76.15.

At 7 A.M., prior to receiving injection, No. 3's respiration was 16; temperature, 98.7°; pulse, 78. At 8 A.M., forty-five minutes after injection, temperature, 99°; pulse, 76. At 1 P.M., respiration was 16, temperature, 98.5°; pulse, 72. At 7 P.M., respiration, 16; temperature, 98.5°; pulse, 72. At 7 P.M., respiration, 16; temperature, 98.5°; pulse, 66. Averages for the day, respiration, 16; temperature, 98.56°; pulse, 69.538.

At 7 A.M., prior to receiving injection, No. 10's respiration was 18; temperature, 98.6°; pulse, 88. At 8 A.M., forty-five minutes after injection, temperature, 98.5°; pulse, 80. At 1 P.M., respiration, 18; temperature, 98.5°; pulse, 76. At 7 P.M., respiration, 18; temperature, 98.5°; pulse, 68. Averages for the day, respiration, 18; temperature, 98.516°; pulse, 73.380.

At 7 A.M., prior to receiving injection, No. 11's respiration was 15; temperature, 98.7°; pulse, 88. At 8 A.M., forty five minutes after injection, temperature, 98.7°; pulse, 66. At 1 P.M., respiration, 16; temperature, 98.5°; pulse, 82. At 7 P.M., respiration, 16; temperature, 98.5°; pulse, 82. Averages for the day, respiration, 15.66; temperature, 98.546°; pulse, 82.769.

The averages for all who received "Cerebrine" (Hammond) were: At 7 A.M., before injection, respiration, 16.5; temperature, 98.625°; pulse, 85. At 8 A.M., forty-five minutes after injection, temperature, 98.8°; pulse, 79.5. At 1 P.M., respiration, 16.25; temperature, 98.525°; pulse, 76.5. At 7 P.M., respiration, 16; temperature, 98.5°; pulse, 70.

It is unnecessary to go over these tables seriatim, as they speak for themselves. It will be seen that Nos. 4, 6, 7, and 12 received "Cerebrin" (Parke, Davis & Co.), and Nos. 9, 2, 5, and 8, a solution of borax, glycerin, and water.

"Cerebrin" (Parke, Davis & Co.), gave very little variation in results from those yielded by "Cerebrine" (Hammond), not enough to be of value on comparison. The third fluid was practically as effective as the two preceding. In no instance was the average temperature increased to the amount of 0.07 of a degree, and the highest average temperature reached was that of No. 12, with "Cerebrin" (Parke, Davis & Co.).

In connection with this it may be well to remark that the slight acceleration of pulse which occurred at the beginning of the experiments, and which was noticed as much before the injection as afterward, was due, probably, to some slight mental doubt on the part of those experimented upon. But the innocuous character of the experiments was pretty well known throughout the concern where these men were employed before the day was over, hence, as a consequence, the second day's experimentation, as shown by Table No. 2, witnessed considerably less variation.

EXPERIMENT No. 2. TABLE No. 2.—Dose, ten minims each of "Cerebrine" (Hammond); "Cerebrin" (Parke, Davis & Co.), and solution of borax in glycerin and water.

It will be observed that the average respiration at 7 A.M., prior to receiving injection, for those receiving Hammond's fluid, was 17.75; temperature, 98.5°; pulse, 80. At 8 A.M., forty-five minutes after the ingestion of the fluid, the temperature was in no instance elevated, and the average pulse had fallen to 72.5. At 1 P.M. the total average respiration was 18; temperature, 98.525°; pulse, 72.25. At 7 P.M., the respiration was 16.75, temperature 98.5°, pulse 69.

EXPERIMENT No. 3. TABLE No. 3.—Dose, fifteen minims each of "Cerebrine" (Hammond); "Cerebrin" (Parke, Davis & Co.), and solution of borax in glycerin and water.

The twelve individuals experimented with on this occasion were selected from those of the two previous experiments. Nos. 1, 3, 9, 8, 6, 12, and 10 being respectively Nos. 3, 2, 8, 9, 1, 12, and 5 of the second experiment, and Nos. 4, 7, 5, 2, and 10 were respectively Nos. 12, 11, 4, 2, and 5 of the first experiment.

Practically the same ratio as in the two preceding experiments obtained.

Further, as to all three experiments, the claims made by Dr. Hammond were in no instance borne out either as to pulse, respiration and temperature, exhilaration, flushing, wakefulness, increased quantity of urine, expulsive force of bladder and peristalsis of the intestines, increased muscular strength, increased power of vision, or increased appetite and digestion.

In addition to all this, I myself ingested on various occasions doses varying from five minims to one-half ounce of both "Cerebrine" (Hammond) and "Cerebrin" (Parke, Davis & Co.), without any appreciable effect; and so far as the assertion that a dose of "Cerebrine" (Hammond) induces insomnia is concerned I am obliged to dissent. One-half ounce ingested at 8.30 P.M. did not in the least influence sleep, which was profound an hour and a half later.

There is but one conclusion to be formed, viz., that "Cerebrine" (Hammond), "Cerebrin" (Parke, Davis & Co.) so-called, and a solution of borax in glycerin and water, are equally efficacious —or rather equally inert for good or evil.

CATHETERIZATION OF THE FALLOPIAN TUBES.[1]

By O. B. WILL, M.D.,
of Peoria, Ill.

In a paper read at the last annual meeting of this Association I alluded to some personal experience in catheterizing the Fallopian tubes, or, more accurately speaking, in making direct medicinal applications to the interior of those appendages. The subsequent interest and favorable comment elicited, together with the widespread disbelief in the possibility of such procedure, revealed by investigation into the literature of the subject, have impelled me to a further brief consideration of the matter at the present time.

In the course of my experimental ventures I had no thought of experiences either specially unique or particularly novel, thinking the procedure a natural result of an acceptance of the modern theory of contagion and continuity, as applied to the etiology of tubal disease, and antisepsis and drainage in its therapeutic relationship. I was surprised to find, on investigation, so great a dearth of literature on the subject. In all the leading text-books, society Transactions, and periodic literature at my command, nothing whatever on the subject is even hinted at, except in Dr. Henry C. Coe's article on "Anatomy of the Female Pelvic Organs," in the *American System of Gynecology*, in which he says, briefly: "Catheterization and cauterization of the tubes, as proposed by Tyler Smith and Froseip, are of course of no practical value, not to speak of the difficulty and danger of the procedure." In the great work of Pozzi reference to the matter is made also as follows:

"Is it possible to pass the sound into the Fallopian tubes? This is the explanation of some authors in those cases where the instrument penetrates deeply into the abdomen, and can be detected through its wall. That this may occur there must be a combination of very unusual circumstance—a latero-version of the uterus, which brings the orifice of the tube into the long axis of the cervix, and an exceptional wideness of its opening. This condition actually existed in a case observed by Bischoff, and was verified after death following ovariotomy. But in almost every one of the published cases of pretended sounding of the tubes, it is far more likely that there was a perforation of the uterus—a condition which is easily produced without exaggerated efforts when the uterus is softened and thinned from pregnancy or recent abortion, or when it is displaced. The benign character of such wounds has surprised most of those who have witnessed their production, and has induced them to seek an explanation which appears more plausible. This is without doubt the significance which must be given to two cases recently reported by Gonner, of Basel. Finally, we may note the possibility of establishing permanent false passages, and the introduction of the sound by the same route into the abdominal cavity. But these are, in truth, but pathological curiosities, with which we have very little to do."

Thus it will be seen that Pozzi expresses his doubts, not only as to the reliability of evidence offered, but even as to the possibility of such a procedure, except as revealed by post-mortem examination. If the latter opportunity had never manifested itself, he would probably never have accepted the evidence of the observer quoted in that connection. If the circumstance, indisputably proved, occurred once, may it not occur a second time, and if so, a third, and so on, as attention should be more particularly turned to the matter? Facts are oftentimes not discovered, simply because they are not sought for. The fact that the normal uterus and appendages present positions and conditions usually not favorable to the passage of a foreign body into their cavities, does not militate against the possibility of differing conditions in cases of disease and malposition.

Whatever may be the published or unpublished experience and views of others, however, I feel that I am in a position to take successful issue with those who think the difficulties of the manipulation insurmountable and the procedure impractical. There is not the least particle of doubt in my own mind as to the accuracy of conclusion of those who have reported accidental entrance of the sound into the Fallopian tube. I feel that I might go still further, and say with a degree of propriety equal to that of the author quoted, that the instances of perforation of the uterine wall without apparent effort were in all probability instances of unconscious catheterization of the Fallopian tubes. To my mind, the one insinuation is just as fair and well-founded as the other.

As many as fifteen years ago, whilst endeavoring to outline a submucous fibroid growth of the uterus, I found my sound pass at once to an unusual depth, and in great trepidation and alarm I put my patient to bed, fortified with opiates and prospective cold applications, under the impression that a perforation of the uterus had been made and peritonitis was to be feared. There was no development of inflammatory symptoms, however, and I classed the case in the category of those referred to by the author quoted, considering it an evidence of the tolerance manifested by the, at other times, intolerant peritoneal tissue. There was not even pain, and the patient persisted in the declaration that there was nothing the matter with her, and would not remain quiet. Some time later, in a case of hemorrhage, a similar occurrence took place with respect to the passage of

[1] Read before the Illinois State Medical Society, May, 1893

the sound, without any resulting untoward symptoms, although the patient was not put to bed but only admonished to keep quiet and report at once the development of pain or the like. About four years ago another case presented in the person of Mrs. K., a butcher's wife, large and stout, who had not been pregnant for half a dozen years, although anxious to become so and desirous of knowing the reason for her barrenness. I passed a small sound, quite gently, and was surprised to find that with but slight manipulation the instrument largely disappeared in the direction of the left cornu, evidently entering the abdominal cavity. Somewhat startled, I at once withdrew the instrument, with perfect ease, and inquired of the lady if she had suffered any pain from my manipulations. She assured me that she had not, and after plucking up more courage and giving the matter some thought I reintroduced the sound, not only into the uterus but likewise to a greater distance and in the same direction as before, and with equal ease and freedom from pain or distress. Somewhat emboldened by the apparent harmlessness of the venture, I cautiously manipulated the instrument with one hand, and by palpation with the other, alternately internally and externally, I satisfied myself that I had succeeded in introducing the sound into the left Fallopian tube. The woman left my office and returned to her home as well as usual. When she again called, at my request, my curiosity led me to a still further trial of the matter, with a like result, and with the additional one of passing the small sound, with some difficulty, however, into the right tube as well. This passage of the sound I have repeated a number of times in this patient, completely establishing the perfect feasibility, in some cases at least, of catheterization of the Fallopian tubes. This patient is yet within my reach and I can demonstrate on her, to the satisfaction of anyone, I think, the possibility, in certain cases, of introducing even a large sound into the Fallopian tube, through the normal uterine passage, and with little more than the slight curve usually characterizing the uterine sound. In the instance just mentioned the uterus is large, straight, somewhat retroverted, and the cervical canal large and roomy. Patient has never become pregnant.

One other marked case of this type came under my observation about one year and a half ago, in the person of a Jewess who, at that time, presented all the evidences of a tubal pregnancy. Menstruation had been suppressed for three months, and the enlargement, plainly distinguishable in the right uterine cornu and broad ligament, satisfied me that I had to do with a partial extra-uterine pregnancy. Hemorrhage, fitful in character, soon supervened and increased with such rapidity and severity that I was obliged to dilate the uterus and remove from its right cornu and tube-entrance what proved to be the product of conception, with the closely adherent placenta partly projecting, as I think, into the tubal cavity. At all events, a large uterine sound could be easily passed into the tube, and a smaller one with comparative readiness into the left one. The same manipulation can be accomplished at the present time, as I yet have the patient under my care for a constant discharge evidently emanating from the right tube and dating from the period of the pregnancy just recounted, and which I have thus far been unable to wholly control even by the use of injections of hydrogen dioxid, which are readily given, the fluid, however, passing into the peritoneal cavity if used in quantity, occasioning some pain and distress.

I have no doubt that some of my experience has been duplicated in the observation of others, and I hope that this account may serve to bring out such reports, even if a supposed mistaken diagnosis, or timidity in the face of authority, has thus far prevented this.

Since the experiences detailed, I have sought to embrace nearly every suitable opportunity to try the experiment of catheterization, and particularly so since the introduction of the practice of uterine drainage and therapeutic antisepsis. In a fair proportion of cases I have been enabled to do so successfully. I not only make this claim, but stand committed to a willingness to demonstrate the feasibility of the procedure, in suitable cases, to the satisfaction of anyone who cares to take the pains to corroborate what I say by personal observation.

All medical men will perhaps acknowledge the demonstrable egress and ingress of fluids in relation to the patulousness of the utero-tubal opening. What, then, is there to hinder the introduction into such opening of a suitable instrument? In a direct way, manifestly only the normally small diameter of the orifice. If this obstacle can be overcome in any way, serious interference with the procedure can be expected only in one or both of two directions, viz., the possible existence of a valve-like membranous enclosure, or, such relation of the angle of tubal insertion to the entrance axis of the uterus as to make the cavity of the tube inaccessible, no matter what its lateral dimensions.

Let us consider this matter for a moment. The regular triangular shape of the uterine cavity is presented, with the uterine os at one, and the respective tubal openings at the other two, of these angles. There is no special difficulty, even in strictly normal uteri, in reaching either tubal angle through the cervical opening. The only possible hindrances then to the procedure under consideration are those just referred to. That they are not always present is evidenced by the observations of myself and

others, just detailed. That they may be in many cases artificially overcome is equally demonstrable. The variation in size of the tubal meatus in different individuals, and under differing circumstances and conditions, and the mobility and adjustability of all the organs concerned, including the dilatability of the uterine os, render it possible to temporarily adjust positions and harmonize axes to an extent equal to most emergencies. It is unnecessary in this connection to go further into a description of anatomic conditions with which all intelligent physicians are familiar.

On subjecting a patient to the ordeal of an attempted catheterization of the Fallopian tubes, I am in the habit, as stated in my former paper, of first passing a small-sized sound, and with its bulbous point locate the ultimate limit of the tubal angle of the uterus. This is followed by the injection-tube of a Molesworth uterine dilator, which I have found in extremity to be a very efficient instrument for the purpose, bent to correspond to the shape of the withdrawn sound. This tube is made to follow the mental calculation as to direction marked out by the sound. If no entrance can be readily effected, a calculation based upon careful examination of relative positions must be made as to the necessity for dilating, or trying to change the relationship of the uterus, so as to admit of a proper adjustment of opening to opening. In at least a fair proportion of cases care and perseverance will be rewarded by a success demonstrable in all fulness by the injection of some innocuous fluid that will either distend the tube to an appreciable extent, or occasion an abdominal pain of sometimes circumscribed and at other times diffused character, but harmless. Really, one who has never tried it will be astonished to find with what ease entrance can occasionally be made, particularly in some cases of relaxed uteri and profuse, though simple leukorrheal discharge. It is not claimed that this desirable accession can be secured in all, or even in a majority of cases, but only that there are many in which the procedure can be accomplished, and that, too, with the greatest benefit from a therapeutic point of view. In fact, the practical value of these observations lies in their therapeutic relationship; and that does not necessarily mean either free drainage, cauterization, or the introduction of dangerous medicaments. It means more in the line of modern therapeutics and specific medication. It means sterilization in the sense of the exclusion or destruction of morbid entities and products; etiologic factors of continuous septic infection and diseased tissue-change, and subsequent reliance upon the restorative energy of the natural processes. It means a rational and conservative therapeusis in which is recognized the legitimacy of drainage and other antiseptic precautions in the treatment of diseases of the endometrium, and the logical sequence of following diseased conditions beyond that boundary into a well-recognized field of morbid activity.

My observations in this direction have not as yet carried me very far. Two classes of cases, however, clinically speaking, I have been enabled to treat with the greatest satisfaction by catheterization and injection into the Fallopian tubes. When there exists a persistent leukorrheal discharge of a catarrhal type, even in unmarried women, which even intra-uterine medication fails to control, I have often been enabled to stop it entirely by the use of injections of hydrogen dioxid into the Fallopian tube; for the fact is demonstrable that it is in just this very class of cases that the tubal meatus is found to be most patulous. It is not necessary that the injection-tube be introduced more than through the isthmus in order to accomplish the desired purpose. Beyond that point the increasing diameter of the Fallopian tube readily admits of the exudation of the hydrogen dioxid through the small eyelets near the end of the catheter I have mentioned. The other class of cases referred to is that in which we find intermittent discharges of pus from the uterine cavity, those cases in which the patients give a report of more or less frequently recurring "ruptures" of "ulcers" or "abscesses"—"breaking" of them, as they sometimes say. Unquestionably these are cases of pyosalpinx in which the distal extremity of the tube has been closed by adhesions, whilst the uterine end is yet not sufficiently occluded to bear the strain of accumulating pus. In my experience, a goodly number of these cases can be successfully treated in the manner indicated, in combination with other conservative measures that might be dwelt upon. Of course, when much disorganization is present, or a series of cavities has formed, or when the ovary itself is diseased to the extent of disorganization, no reliance should or can be placed upon the procedure now under consideration. What I wish mostly to urge is this: That the Fallopian tubes are far more frequently amenable to catheterization than is generally supposed, and that therefore, in the light of modern therapeutics, a persevering and intelligent study of the subject will do much to remove one of the opprobria of medical art and add laurels to truly scientific conservatism.

TWENTY-EIGHT CASES OF DIPHTHERIA, WITH ELEVEN DEATHS, DUE TO AN INFECTED MILK-SUPPLY.

BY FRED. B. APPLEGET,
SPECIAL HEALTH-INSPECTOR, OF HIGHTSTOWN, N. J.

THE epidemic of diphtheria that appeared in Hightstown, N. J., in July, 1893, was, in many respects, a remarkable one. From its suddenness, its virulence, and the quickness with which it abated, it has excited widespread interest, and has been deemed especially noteworthy as a signal case of the spreading of disease through the medium of milk, and of the immediate and almost complete extinction of the epidemic by cutting off the infected supply. Hightstown is a village of some 2000 inhabitants, and lies in one of the most healthful parts of Mercer County. There had been occasional cases of mild diphtheria in the town during the year, and one death from the disease on June 17th, but the first case of the epidemic in question appeared on July 18th, the patient being a young boy of fifteen years. Other cases appeared almost simultaneously, and at the end of the week a total of twenty-eight patients had been reported. Of these six died. The first two deaths occurred on the 22d, one of them being the boy first attacked. One death followed on the 23d, one on the 24th, and one on the 25th. In the next week two deaths occurred on the 26th, one on the 28th, one on the 29th, and one on the 30th. One other victim of the epidemic was an infant, whose parents took it to Eatontown on the 17th, to escape the disease, but who sickened, and died on the 28th. The total number of deaths was eleven, all of them being among the patients stricken in the first week of the epidemic. Outside of those who were prostrated by the disease in that period there have been but seven cases reported, all being persons known to have been directly subjected to contagion from original cases.

The fatality was in the main among children, the oldest person that died being a young lady of nineteen years, the youngest a babe of fifteen months. The average age in the fatal cases was about eight years.

On the 25th the attention of the local Board of Health was first called to the fact that there was a striking coincidence between the course of the epidemic and the milk-route of one dairyman, but no action was taken in the matter until Dr. G. Clark Hunt, Inspector of the State Board of Health, visited the town on the following day. Investigation showed that, although the people of the town bought milk from six different dairymen, every case of diphtheria reported was in a family that used the suspected milk. In one instance, in which the adults of a family used this milk, and the children drank milk from another dairy, two of the adults had diphtheria, while the children were perfectly well. The sanitary condition of the town while not perfect, was found to be very good, and the cases were almost all in the most cleanly families, had sprung up in the healthiest parts of the town, and were widely scattered. In the opinion of Inspector Hunt the milk-route was the only possible connection between them, and he immediately ordered that further sale of the milk be prohibited. Developments have proved that his theory was correct, and all the local physicians are positive in their belief that the milk undoubtedly was the source of the epidemic.

Further investigation disclosed the fact that a German boy who washed cans and did the milking at the dairy in question had on the 22d called on a local physician, who found the boy's throat covered with membranous patches. He pronounced the case diphtheria. The boy had been ailing for several days, and it is supposed that while at work he contaminated the milk, and that in this congenial soil the germs rapidly multiplied and infected the entire supply. An additional fact that strengthens the theory is that of the only two other cases known out of the village, one was the daughter of the dairyman and the other his niece, a neighbor.

A striking feature of the case is that the sick boy, who is supposed to have caused the epidemic, was not seriously ill at any time. When the doctor examined him his tonsils were covered with pseudo-membrane, but it soon disappeared after a little treatment, and he was not confined to his bed at all. It, therefore, appears that this most malignant epidemic originated in a case of "walking diphtheria." Naturally, there are theories that the milk was infected by diseased cows or unwholesome food given them, but the herd has been pronounced by experts to be in fine condition at present, and there is little doubt that the disease came from the boy.

As regards the individual cases, the disease does not seem to have had any features to distinguish it from other epidemics of malignant diphtheria, beyond its remarkable virulence and the slowness with which the patients recovered. In fatal cases the longest time of sickness was seven days, and the average was about four. In most of the patients the disease first manifested itself by nausea, pains in the limbs and head, and high temperature. Then followed the appearance of the diphtheric membrane, in many cases covering not only the tonsils, but also the roof of the mouth and the nares. In almost every instance death was caused by toxemia, although there were several cases of asphyxia. When the disease resulted fatally, death was generally preceded by a deceptive rallying of the patient, and several who, only a few hours before were thought to be recov-

ering, died suddenly. Convalescence was remarkably tedious, the patients giving evidence of great loss of vitality. In the few cases caused by contagion the disease assumed a very mild form. At present there are no serious cases.

CLINICAL MEMORANDA.

THERAPEUTIC NOTES.

By SOLOMON SOLIS-COHEN, M.D.,
PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS IN THE PHILADELPHIA POLYCLINIC; ONE OF THE PHYSICIANS TO THE PHILADELPHIA HOSPITAL, ETC.

IV.

Levulose in Diabetes.—Attracted by the favorable reports of German observers, I have for more than a year been administering levulose to diabetic patients. I shall elsewhere publish a detailed report of my observations. In these notes it will suffice to say that in nine cases, including different types of the affection, I have found that levulose may be administered in moderate quantities to diabetic patients without increasing the excretion of sugar or of acetone in the urine; and in some cases with a diminution of the quantity of sugar excreted. For example, to a patient who had for some time been excreting about four ounces of dextrose daily, one or two ounces of levulose were given daily for three weeks, and the excretion of dextrose fell to less than three ounces. Diminution of thirst and gain in weight were concomitantly observed. In cases attended with emaciation, the substance should be administered in quantities to be determined according to the amount of sugar excreted, and the influence exerted upon the nutrition, as shown by the body-weight. In other cases it may be used as a sweetening agent. The greatest drawback to its use is its comparative costliness; the commercial product, to which unfortunately a trademark name has been attached by the proprietors, retailing at present for about three dollars a pound. This, however, is a great reduction from the cost of levulose when Kuelz first advised its use twenty years ago. One hundred dollars a pound was prohibitory.

Strontium Bromid is one of the newer drugs that has held its place. I have used it constantly for nearly two years, and find it to deserve the encomiums of the French observers who reintroduced it into medicine. In a few instances in which I failed to specify the imported salt, patients complained that the medicine produced nausea and gastric pain. On dispensing the pure drug from a quantity obtained by myself from the manufacturers' agents, the complaint was not repeated. It is necessary, therefore, to specify a preparation known to be pure; and after using a number of brands, I have returned to that made in Paris, and with which the experiments of Paul, See, and others, and my own first observations were conducted. I usually give the drug in solution according to the following formula, known in the House Pharmacopeia of the Philadelphia Polyclinic as "mistura strontii bromidi composita":

Strontium bromid, pure, .	1½ ounces.
Glycerin	2 fluidounces.
Infusion of gentian . .	10 fluidounces.

Dose—From two to four fluidrams (fifteen to thirty grains of strontium bromid) before meals.

Strontium, one of the chemic group termed "alkaline earths," appears to have a special action upon the gastric mucous membrane. It increases appetite, promotes digestion, and favors nutrition. It is a distinct sedative in the case of irritability of the stomach.

In cases of chronic gastric catarrh, with a tendency to vomiting, in the nausea and vomiting of alcoholism, and in the indigestion of pulmonary tuberculosis, strontium has been more than ordinarily useful. In gastro-duodenal catarrh, and in intestinal indigestion of painful type, I have given it with some pancreatic preparation, one and a half or two hours after meals. Thus: Liquor pancreaticus, 2 fluidrams; strontium bromid, 15 grains; water, 2 fluidrams. I have likewise employed it with great benefit as an alkaline medicament in the treatment of lithemia. Its sedative effect as a bromid was especially marked in one case of lithemic dyspepsia associated with glycosuria, in which persistent insomnia had led to a distressing sulfonal-habit. By using it in doses of thirty grains during the day, and giving one or two doses of sixty grains at night, with occasional additional resort to hyoscin hydrobromate, the sulfonal-habit was broken up; and as general improvement took place, the insomnia disappeared, and the doses of strontium bromid were reduced. As a bromid, when the drug is to be employed for prolonged periods and in full dosage, the strontium salt is to be preferred in most cases to the potassium or the sodium salt, as it interferes less with nutrition.

I have observed good effects in epilepsy from the conjoint use of calcium and strontium bromids. I have elsewhere reported in some detail my personal observations of the beneficial action of strontium bromid in diabetes and the glycosuria of lithemia. I have found it useful in nephritis of the gouty type, and in the albuminuria associated with lithuria and oxaluria; in three cases of other varieties of nephritis and albuminuria I have used it faithfully, but without appreciable result.

Strontium Lactate has been advised for many kinds of gastric disturbance. I have employed it alternately with the bromid, in combination with the bromid, and alone in some cases in which I did not wish to give any bromid. It has not seemed to me to be fully equal to the bromid in gastric or lithemic cases. I have not used it in diabetes or neurotic cases. In nephritis it failed in the same cases wherein the bromid failed.

Strontium Iodid has been well borne in a few cases of asthma and of syphilis in which sodium iodid, potassium iodid, and hydriodic acid produced unpleasant effects. It failed to be tolerated in one case in which hydriodic acid was afterward successfully employed.

Strontium Benzoate, Strontium Acetate, and Strontium Salicylate should theoretically be useful, but I have not been able to obtain these salts for clinical study.

Sulfonal.—While it is now well recognized that sulfonal occasionally produces unpleasant symptoms, yet the sulfonal-habit and the bad effects of that habit have not as yet received the full attention that they merit. My own experience with the unpleasant effects of sulfonal is limited to three cases; though I have seen other cases in which I suspected sulfonal to be one of

the morbid factors, but could not ascribe any definite symptoms to it. Theoretically, any drug capable of the therapeutic and toxic effects known to be produced by sulfonal should be dangerous if its use be long-continued.

The first case, elsewhere reported, was that of a man slowly dying with pulmonary tuberculosis, in whom sulfonal, given as a hypnotic, produced, instead of quiet sleep, a "fighting delirium." The second case was that of the man alluded to in the note on strontium bromid. He had been taking from fifteen to thirty grains of sulfonal nightly for nearly two years. He professed himself to be unable to sleep without it. His urine was irregular in quantity, but, as a rule, scanty, high-colored, containing urates and phosphates in excess, uric acid, and occasionally sugar. He complained of great pain in the lumbar region; but was principally distressed by mental symptoms, irritability of temper, headache, confusion of ideas, and loss of memory. He had originally been given sulfonal by his physician for loss of sleep during the excitement of a political campaign; and had continued using it on his own responsibility. It is true that the complications of the case prevent an unqualified affirmation as to the part played by the causative action of any one pathogenetic factor, but a careful study of the patient and of the effect of remedies, convinced me that the scantiness of the renal secretion and a part of the mental failure were to be attributed to the long-continued influence of sulfonal.

The third case was that of a highly neurotic woman with pulmonary tuberculosis, who had been using sulfonal in doses of from ten to thirty grains at irregular intervals for an indefinite number of years—probably from the time of its first introduction. Whenever she had headache or whenever she failed to sleep soon after going to bed, she would take a powder. In this case also, without any evidence of nephritis, there was marked failure and irregularity of renal activity. The patient was querulous, forgetful, untruthful, confused, semi-delirious, the subject of delusions, and finally delirious, stuporous, and comatose. Here, too, there was difficulty in separating the symptoms of the disease and its complications from those due to the sulfonal-habit, but a study of all of the circumstances impressed me with the conviction that sulfonal was largely responsible for the distressing symptoms attending the close of this sufferer's life.

A fourth case may be cited as illustrative of a large number in which the evidence was less clear than in those previously mentioned. The patient was a "sexual hypochondriac," with lithemic symptoms and much-disturbed mentality. He had been using sulfonal for eighteen months, and likewise professed inability to sleep without it. The urine would be scanty for days, then profuse, light-colored, and of low specific gravity. He seemed better for a while after withdrawal of the sulfonal, but like most patients of his class became dissatisfied, and when last heard of was under the care of the fourth physician whom he had consulted in six months.

Dr. John W. Branham, a surgeon in the United States Marine-Hospital Service, died on August 19th of yellow fever, at Brunswick, Ga., whither he had been detailed for the purpose of suppressing a local outbreak of the disease.

DOES PHENACETIN POSSESS CONVULSIVANT PROPERTIES?

BY H. ILLOWAY, M.D.,
OF CINCINNATI, O.

CAN phenacetin cause convulsions?

CASE I.—July 30th, 1892, I was called to see E. S., a girl, eighteen years old, well developed and rather corpulent. She is a native of Russia, and has been in this country about a year. For some months after her arrival here she was troubled with amenorrhea. She is now employed in a cloak-making establishment and works very hard. In the afternoon of the day mentioned she was seized with a very severe headache and went home. I saw her at 5 P.M. She complained of intense headache; her cheeks were somewhat flushed; her tongue was very much coated; the thermometer in the axilla indicated a temperature of 101° F. I prescribed one powder of phenacetin, gr. v, to be taken as soon as obtained. About 7.30 P.M., I was summoned in haste to the patient. She had had a violent convulsion. Whilst I was talking to her she had another convulsive seizure; it was a well-defined, typical, hystero-epileptic convulsion. I prescribed tincture of valerian in ʒss doses and ordered a large clyster with milk of asafetida. The spasms recurred at short intervals and I endeavored to arrest them by pressure over the ovaries. This maneuver was successful to the extent that each individual spasm was cut short. As soon as she felt a seizure coming on, she would cry out, "Hold me, or press tighter," referring to the abdominal pressure.

Finally after several doses of valerian had been taken and the enema had acted several times, the spasms ceased about 11 P.M. To prevent a recurrence of the attacks I directed a dose of chloral hydrate.

The next morning I learned that there had been no recurrence of the convulsions after I had left. She was very much prostrated, and I sent her to the Jewish Hospital, where she remained four weeks, with no particular ailment—only great weakness. An examination there disclosed an infantile uterus.

I have since learned that she had had convulsions some years previously, though of what character I could not determine.

CASE II.—On August 3, 1892, I was called to see Mrs. T., thirty years of age, five feet in height, fairly well developed, the mother of three children born with easy labors. My visit was made nine days after confinement, the woman having been up and about from the seventh day. She complained of feeling badly; she had chills, with numbness of the tips of the fingers, coldness of the feet, and an uncomfortable feeling about the head. She had a languid, weary expression; her tongue was coated with a white fur; the appetite was abolished; she had some tremor, and a temperature of 101½° F. I prescribed:

℞.—Quininæ sulphat. . . . . grs. ijss.
Extr. gentian. . . . . gr. j.
Pulv. piper. nigr. . . . . grs. ij.
Solut. Fowleri . . . . . gtta. ij.
M. ft. mass. et ft. pilul. no. j. Dispens. tal. pilul. no. x.
Sig.—1 pill ter in hora.

Next morning, about 9 o'clock, I visited her upon call.

She complained of violent headache; the temperature was 101° F., and she felt generally bad. I prescribed:

℞.—Phenacetin. . . . . gr. v.
Caffein. . . . . gr. j.
M. ft. pulv. no. j; to be taken at once.

At her request I promised to return at 11 A.M., at which hour she complained of feeling bad. Whilst I was talking to the nurse, making some inquiries about the bowels, urine, etc., she got out of bed and walked toward me, with her hands held in front of her, like a person walking in the dark, and complained that she could not see and that she felt frightful. We had no more than put her back into bed when she was seized with a very severe, typical hystero-epileptic convulsion of considerable duration. As soon as she recovered therefrom she passed a quart or more of urine very pale in color and light in specific gravity. Potassium bromid in large doses was administered. Two further seizures of equal severity followed in rapid succession. After this there was no recurrence. For six weeks after this Mrs. S. was not well, suffering from indefinable feelings in her head which produced great mental depression, almost melancholia, insomnia, etc. Gradually, however, she made a perfect recovery. I learned later that on the eighth day after her confinement, at the circumcision of the little boy, something had occurred that had agitated her greatly and had set her in fear of the occurrence of something untoward

Studying these cases subsequently the question naturally presented itself: "Was the spasmodic seizure in these two cases due to the phenacetin, or was the administration of this remedy only an incident in the history of the cases, with no part in the causation of the convulsive phenomena?"

Taking into consideration the well-established fact that phenacetin is almost innocuous, and that it can be, and is, administered in much larger doses without producing untoward effects, the latter view might be taken, it being assumed that all the necessary conditions for the development of a convulsive seizure were already present at the time of the administration of the drug, and that this would have occurred even if the medicine had not been given. This would be a very plausible explanation if we had but Case I, in which we have a history of the occurrence of convulsions at some previous time, to contend with; but we have also Case II, and here we have no history of convulsions at any antecedent period; furthermore, I have known the lady for nine years, and never, to my knowledge, did she manifest any symptom of hysteria or spasm. In this case we certainly have no grounds upon which to base the assumption of the existence of the conditions necessary to the development of a hystero-epileptic attack prior to the administration of the phenacetin.

A scrutiny of the two histories discloses the following points of similarity:

I. Elevation of temperature.

II. Intense headache.

III. Administration of five grains of phenacetin and the development two hours thereafter of an hystero-epileptic spasm.

IV. Marked physical prostration and mental depression following the attack and continuing for some time.

Taking all the facts, here set forth, in consideration, the conclusion seems inevitable that the phenacetin was the active agent in the causation of the convulsions.

If this conclusion be correct, what was the *modus operandi*? In experimental investigations with antipyrin and resorcin, substances belonging, with phenacetin, to the same chemical group—"carbon compounds of the aromatic series,"—convulsive phenomena were developed in the trial-animals,[1] and with resorcin in man.[2] It is thus established that in sufficiently large doses, this group of chemical agents may act as convulsivants. Now, it does not appear far-fetched to assume that under certain circumstances a state of the system is developed in which even the very mildest of this category of compounds, the most innocuous, even if given in small doses, may act as a toxic agent and cause convulsions. Such an assumption is fully justified by the accumulated experience with other and various powerful agents of the Pharmacopeia.

There is, however, another explanation possible. The rapid lowering of the temperature by phenacetin may have been the cause of the accumulation in the cerebral centers of a surplus of nervous irritability, and as the result of this accumulation a nervous explosion, a convulsion, ensued.

It is true that no facts, even remote, can be cited in support of this hypothesis; nevertheless it merits consideration upon the following ground: It is a well-established fact that the onset of a febrile movement is usually marked by a chill or a rigor, which is undoubtedly due to disturbance of the nervous equilibrium; furthermore, in very young children we frequently have convulsive seizures taking the place of the chill or rigor. Now, reasoning by analogy, it can be rather readily supposed that just as well as a sudden elevation of temperature may be attended with marked nervous disturbance, so may also a rapid and forcible depression of the temperature be attended with sufficient nervous disturbance to result, under certain circumstances, in convulsions.

MEDICAL PROGRESS.

A Foreign Body in the Nose for Twenty-seven Years.—Waring (*British Medical Journal*, No. 1698, p. 117) has reported the case of a woman, thirty-one years old, who presented herself for nasal obstruction and a discharge from the left nostril, following upon an attack of influenza two and one-half years previously. The discharge, at first watery, later became thicker and yellowish, with an extremely offensive odor. There was no evidence of organic disease and none of syphilis or tuberculosis. Upon examination in strong sunlight the nasal cavity presented an appearance of decaying or necrosing mucous membrane, with yellow and gray sloughy patches, and indications of hyperemia. The opening was blocked by this conglomerate of decaying material and reddened vascular membrane. On passing a probe into the cavity a grating sensation was felt on the outer side and also posteriorly, and the further

[1] Baumann u. Preusse: Archiv f. Anatom. u. Physiolog., 1877.
[2] Maragliano: Centralblatt für die medic. Wissenschaft, 1884.

passage of the probe toward the pharynx was obstructed. By means of straight serrated forceps small spicules of dead bone and sloughing tissue were removed piecemeal from the outer side and floor of the cavity, as well as several polypoid growths of somewhat firmer consistence than clotted blood. Almost in a line directly backward and situated above and about the posterior nares was a movable mass that felt like dead bone. With some difficulty and manipulation this mass was grasped by the forceps and forcibly withdrawn through the left nostril. It was oval in shape, about as large as a filbert, and presented an irregular, gritty surface. On being broken up it was found to have for its nucleus a cherry-stone in perfect condition, around which was encrusted a layer of calcareous matter one-third of an inch thick, the whole mass measuring one inch in its longest diameter. A good deal of bleeding followed, but was controlled by irrigation with a solution of tannic acid. On inquiry, it was learned that at the age of four years the patient had introduced three or four cherry-seeds into the nose, but no discomfort had been felt until after the attack of influenza.

The Use of Curved Skin-incisions.—BEALE (*Lancet*, No. 3645, p. 84) gives the following reasons for preferring curved to straight skin-incisions: Curved incisions heal more rapidly, because there is really but one edge to the wound (that belonging to the flap) that is movable; moreover, the flap having been stitched to the neighboring skin or held away from the seat of operation, both edges of the wound are quite uninjured when the sutures are to be introduced. The resulting scar is smaller, although this is only of importance in certain parts, for the skin may be incised obliquely in making a curved incision, so that the epidermis at the edge of the flap is slightly in advance of the true skin. The curved incision fully exposes the parts to be operated on (assuming that the base of the flap is twice or three times its length) and gives the operator plenty of room in which to work. Suture of the edges is easier than in the case of a straight incision, especially if the skin be pricked in one or two situations exactly opposite one another before the incision is made, and often the curved wound is adapted to the shape of the part better than a straight one. The resulting cicatrix is not over the seat of operation. Drainage is often most perfect by inserting a tube through an incision in the base of some part of the flap, thus giving no hindrance to the primary union of the incision, and preventing any possible discharge from infecting the edges. Incision through inflamed or diseased skin can be avoided, and yet the disease be easily reached. There need be no tension upon the edges of the wound, as a flap of skin is, so to speak, loose, and if there is fear of tension, a thick silk suture may be passed through the base or some part of the flap and out again, and then through the skin on the opposite side of the incision, and there fixed, thus avoiding a long suture beneath either flap edge of the wound.

Acute Nephritis after Vaccination.—PERL (*Berliner klin. Wochenschr.*, No. 28, 1893, p. 674) has reported the case of a child, two and three-quarters years old, which was vaccinated for the first time. The child had been rachitic, slow in learning to walk, and had suffered a good deal with eczema, but at the time of the operation it was in perfect health and well nourished. Four days later the little one became restless, complaining of pains in the abdomen and back and appearing feverish. On the following day vesicles were visible at the site of vaccination. It was also noticed that the urine was scanty, turbid, brownish, and deposited a heavy sediment. On examination, its specific gravity was found to be 1016, and albumin in the proportion of ½ per cent. was detected, together with blood coloring-matter. Microscopic examination disclosed the presence of red and colorless blood-corpuscles and numerous hyaline, epithelial, and blood tube-casts. With rest in bed and a milk-diet these manifestations disappeared in the course of a week, and the child recovered perfectly. The vaccination pursued its usual course. Three other children that were vaccinated at the same time presented no abnormal manifestations.

Migraine with Recurrent Palsy of the Third Nerve.—At a a recent meeting of the Ophthalmological Society of the United Kingdom, SNELL (*British Medical Journal*, No. 1698, p. 118) reported two cases in which attacks of migraine were attended with paralysis of the third nerve. One case was in a man, twenty-seven years old, who had had attacks of migraine from the age of ten years, during the last seven of which the eye had been closed in the attacks. These occurred at first at intervals of about eight weeks, but subsequently every two or three weeks, and lasted three or four days. The palsy of the third nerve was practically complete, there being ptosis and paralysis of the ocular muscles, including dilatation of the pupil and palsy of accommodation. The attacks commenced with vomiting and headache. In the intervals between attacks the ocular palsy did not entirely disappear, the drooping of the lid growing progressively more nearly permanent. The second case was in a girl, eighteen years old, in which two attacks of palsy occurred at interval of four years, though outbreaks of migraine in the interval. On each occasion recovery was perfect. The affection is always to be monocular. The rapidity of recovery seems to bear an inverse ratio to the length of the interval.

The Administration of Anesthetics.—The following deductions (*Lancet*, No. 3642, p. 1498) have been arrived at by the Commission appointed by the *Lancet* to investigate from a clinical standpoint the subject of the administration of chloroform and other anesthetics: The death-rate under anesthetics has heretofore been unduly high, and may be lowered by improved methods and greater care. Ether is the safest anesthetic in temperate climes for general surgery, when properly given from an inhaler permitting graduation of the strength of the vapor. Nitrous oxid gas should be employed for minor surgery, and should replace chloroform in dental surgery. Chloroform is a comparatively safe body when given by a carefully trained person, but is not in any case wholly devoid of risk. No age or nation is free from danger under anesthetics. The perils of anesthesia, however slight, demand that the undivided attention of a duly qualified and trained medical man should be given to the administration of the anesthetic.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 26, 1893.

PHLEGMONOUS PROCESSES ASSOCIATED WITH THE PRODUCTION OF GAS.

IT seems at first rather surprising that in view of the well-established facts connected with the bacteriology of the suppurative inflammations, surgeons should have remained ignorant of, and comparatively indifferent to, the nature of those destructive phlegmonous processes associated with the evolution of gas in the tissues. Fortunately, these "septic phlegmons," since the advent of the newer surgical technique, are among the rarer accidents that befall wounds; but despite this fact, the names Spreading Gangrene, Acute Emphysematous Gangrene, and *Gangrène foudroyante* (of MAISSONNEUVE) have by no means yet lost all their terrors.

On reviewing the literature it will be found that general credence has been given to the idea that phlegmons of this sort are dependent for their origin on particularly virulent varieties of the ordinary pyogenic bacteria, especially of the streptococcus pyogenes, and v. WINIWARTER has with some emphasis asserted that "no sharp line can be drawn between the diffuse suppurative and the diffuse septic phlegmons." As a matter of fact, when the tissues in cases of emphysematous gangrene were examined for bacteria, bacilli were always found, sometimes alone, sometimes associated with cocci, but these were almost invariably regarded as saprophytes, or bacteria of putrefaction, and looked upon as accidental contaminations of streptococcus-pus, in which they had found a suitable medium for saprophytic development (v. WINIWARTER, STIERLIN).

EUGENE FRAENKEL,[1] of Hamburg, has recently gone over this whole subject, and, through his bacteriologic investigations, has done much to clear up our knowledge of these processes, and to direct the further study of them along definite lines. He believes, and has, we think, proved that these gas-phlegmons possess a distinctive etiology quite independent of the suppurative inflammations, and calls attention to clinical evidence which alone seems almost convincing when once pointed out. The diffuse suppurative inflammations run their course with necrosis and pus-formation from the start; the diffuse "septic phlegmons" are associated with gas-development, and with softening and disintegration of the tissues. While the former may continue throughout without gas-formation, the latter, on the other hand, may lead to death without the slightest evidence of suppuration, although, as might have been expected, and as has now been demonstrated by cultural methods, *mixed* infections occur in which the development of gas may complicate a suppurative inflammation, or in which a secondary pyogenic infection may be superimposed upon a gas-phlegmon. The tardy appreciation of these conceptions of emphysematous gangrene is no doubt attributable to the deficiencies in the earlier bacteriologic methods, for the bacilli seen in the tissues and exudate could not be grown or isolated in pure culture, and so the application of the crucial test of inoculation-experiments remained impossible. After the introduction of the simpler methods of growing anaërobic bacteria, it became possible for these investigations to be more fruitful.

The idea of a separate etiology for the gas-phlegmons is by no means original with FRAENKEL, and he himself, in his monograph, refers to numerous attempts by others to settle the question. ROSENBACH observed two well-marked cases in which death occurred from gangrenous emphysema, one within six hours after an injury to the thigh, the other four days after an axillary operation. He saw what he called "emphysema-bacilli" in cover-slip preparations, but could not grow them. ARLOING described

[1] Ueber Gasphlegmonen. Hamburg and Leipzig, Leopold Voss, 1893. Pp. 1–56. 3 chromolith. pl.

a gaseous panophthalmitis following injury, from which he isolated a bacillus resembling the *vibrion septique*, and in 1891 LEVY (*Deut. Zeitschr. f. Chir.*, xxxii), from a pelvic abscess which contained gas, isolated, besides streptococci, a short, fine, non-motile bacillus. WILLIAM KOCH (*Deutsche Chirurg.*, Lief. 9) records seven cases, from one of which he claims to have isolated a bacillus identical in cultural properties and in pathogenic effects on animals with the bacillus of "symptomatic anthrax" (*Rauschbrand*), and calls the disease *Rauschbrand des Menschen*, but according to KITASATO and others, who have worked with this bacillus, his results must be doubted.

The careful bacteriologic examinations of WICKLEIN (*Virch. Archiv*, Bd. cxxv) are worthy of mention. From three cases he was able to separate a bacillus which resembled that of malignant edema, but which showed some points of difference from it. His experiments on animals were, however, almost entirely negative, only two guinea-pigs showing any disturbance after inoculation, and that only slight and temporary. CHIARI (*Prager med. Woch.*, 1893, No. 1) has described a fatal case of "septic emphysema" in a diabetic woman. He made both aërobic and anaërobic cultures, and separated the bacillus coli communis in pure culture. His experiments on animals were, however, negative, and it seems not unlikely that CHIARI had to deal with a mixed infection with the bacillus coli and a gas-producing bacillus, and that the latter was overlooked in working out the cultures.

FRAENKEL, to whose results we wish to call particular attention here, has had the opportunity of examining bacteriologically four cases of gas-phlegmon, two of them, indeed, following hypodermatic injections. From all of these he demonstrated on cover-slips, and was able to isolate by anaërobic plate-methods in pure culture, a short, plump, non-motile bacillus, with rounded ends, which stained well with all the ordinary bacterial dyes, and to which he has given the name *bacillus phlegmonis emphysematosa*. In one case this bacillus alone was found in the tissues; in a second it was associated with the yellow staphylococcus; and in the other two instances with the streptococcus pyogenes. He experimented on animals with pure cultures of the bacillus, and with mixtures of this bacillus with the ordinary pyogenic bacteria, in order to approach as nearly as possible to the mixed infections in the human being. Mice and rabbits were found to be insusceptible, but subcutaneous inoculation of guinea-pigs gave rise to a definite disease-picture, running its course in a typical way, with the development of gas in the subcutaneous and intermuscular tissues, accompanied by softening and disintegration of the muscles, and the outpouring of a hemorrhagic, dirty exudate. Some of the animals died with symptoms of severe constitutional disturbance; in others perforation of the skin ensued, with evacuation of the contents of the phlegmon, and final cure. Occasionally a peritonitis or pleuritis would be set up by extension. The "mixed infections" were more severe in guinea-pigs than the processes resulting from inoculation of the bacilli alone. The results of the histologic examination of the tissues of the animals experimented upon, and the relation of the bacteria to the tissue-lesions, we shall not speak of here. FRAENKEL differentiates his bacillus from the bacillus of *Rauschbrand*, the bacillus of malignant edema, and the "pseudo-edema bacillus" of LIBORIUS, but suggests that there may be several varieties of gas-bacilli, all capable of setting up emphysematous processes.

Without detracting at all from the value of these careful researches of FRAENKEL, it is necessary to direct attention to an oversight on his part, which becomes evident from his full description of the bacillus. The organism which he believes to have been before undescribed, has in reality been very fully studied in this country by WELCH and NUTTALL, and an epitome of their observations has already appeared in THE NEWS ("Pneumathæmia," Sept. 24, 1892, p. 357). A comparison of the original articles of the observers shows these two gas-producing bacilli to possess precisely similar cultural and morphologic properties, and there is every reason to believe that they are identical. The animal experiments were conducted differently, but so far as they were parallel their results agree. The bacillus of WELCH and NUTTALL, it will be remembered, was found in a patient suffering from aneurysm, in whom after death bubbles of gas were found in the heart and bloodvessels everywhere throughout the body. Not only on account of priority, but more by reason of its greater comprehensiveness, it would seem desirable therefore to retain for this gas-bacillus the name given it by WELCH, the *bacillus aërogenes capsulatus*.

The dangers lurking behind an ordinary hypodermatic puncture are well illustrated by two of the fatal cases of FRAENKEL, and it is interesting to note

that he succeeded in guinea-pigs in setting up a gas-phlegmon by simply contaminating a hypodermatic needle used for injection with a culture of the gas-bacillus.

Although Fraenkel has, in view of the anaërobic nature of the bacillus, suggested that long and free incisions which allow the oxygen of the air to come in contact with the affected tissues may be of service, and that this treatment may be supplemented by the use of certain oxidizing agents (*e. g.*, solutions of potassium permanganate or hydrogen dioxid), we should still feel inclined to hesitate in preferring these measures to the older and perhaps more heroic method of early amputation, which has so long been advocated by our best surgeons. When amputation is impossible, however, as in emphysematous phlegmons of the head and trunk, these suggestions may be adopted as the best means at our command.

MEDICINE AND CITY NOISES.

Not long since a foolish gentleman, who preferred to live in New York or not to live at all, committed suicide rather than to longer endure the ear-splitting noise of the bells of a neighboring church. In thousands of cases people are being made ill, are committing slow suicide, or are being painfully and slowly killed by useless city noises. Noise, then, becomes a question of health and of medical importance concerning which physicians should have a word to say and a duty to perform.

Scientifically, our rebellion against the noise-makers is founded upon the physiologic truth that rest is necessary to health, and that over-stimulation or persistent stimulation of any organ or of all organs is essentially pathogenic. Herbert Spencer secured for himself a sad sort of freedom from noise by a mechanical contrivance that held some kind of soft plugs or stoppers in the external auditory meatuses. If there were only some method whereby one could at will shut out unwelcome sound, as one can shut out the light from the eyes; if some aurist could devise an artificial method *à la* Spencer, one that would not injure the ear, he would be a great benefactor to humanity. The evil done the few people that would thereby possibly be burned to death or otherwise injured would be small, as compared with that of the many deaths and much sickness due to noise.

Sociologically, the whole community has an unrecognized duty as regards noise that rests upon a physiologic and esthetic basis. Delicacy and accuracy of response to a physiologic stimulus are the characteristic marks of perfection in an organism. Whatever prevents this is against the welfare of society and progress. In this brutal noise-making era, one of two things must follow the ceaseless bruising of the mind by noise. Either the auditory mechanism, and the nervous mechanism with which it is related—that is, the whole mind—must become blunted in sensitiveness, crushed and stupefied; or it must react pathologically. People are, therefore, divisible into two classes: those whose nervous systems and minds are becoming mechanicalized, anesthetic, and brutalized, and those who, thus failing to kill sense and mentality, develop disease-reactions. The distinct agency of noise is to make us either savage or sickly. Civilization, of which noise-making is a decided component, is thus bearing in its bosom a self-poison, to its own undoing. We are losing all refinement and delicacy of the senses and are reverting to the condition of the barbarian whose senses had to be pounded and whipped into reaction, or we are becoming neurotic, hysteric, and neurasthenic. Generally and progressively, "Society" is either a crowd of the mentally stupid or of the hyperesthetically morbid, and social amusement is becoming a game of battering and spurring jaded and blunted senses, or of ministering to sense-diseases.

In the narrowest sense, we are medically bound to reduce the amount of noise-making, not only because noise engenders disease, but also because it prevents the cure of disease, or aggravates disease, very often, indeed, is the immediate cause of death. In an American city like Philadelphia there are something like 3000 needless deaths, and the equivalent of 6000 years of needless illness each year. What proportion of this waste of life is due to noise, it is, of course, impossible to say, but certainly a considerable proportion is chargeable to it. The sick are in private houses scattered all through the city, or in hospitals that are often located in the most densely crowded portions. Every physician knows how necessary quietness is to the sick, and how often noise has been the last baneful influence that the weakened organism could not resist, and thus the controlling and distinctive cause of failure to cure.

The recklessness of production and the unnecessariness of modern city noises are disgustingly astonishing. The worst of it is that they are even

kept up throughout the night. If the night, at least, were kept quiet, and the organism were thus given periods of repose, it would not be so impossible to preserve normality of sense-reaction and sanity of mental reaction. In Philadelphia one or a dozen drunken brawlers may make the night hideous with howl and curse and obscenity. Remonstrance with the policeman elicits a smile, with ill-concealed contempt for the remonstrant as a crank, and the avowal that he has no authority to interfere. In Philadelphia it is illegal for locomotive-engineers to blow whistles, and yet all night long sleep, at least in summer, is to healthy ears and minds impossible by reason of this ear-splitting curse. Street-car bells rung all the time (by horses or by wheels) are no protection to the public, and yet the public submits to the horrible nuisance. The laying of railway-tracks and the paving of streets at night are only necessary for the advantage and profit of mercenary corporations, and yet the authorities have no power, or do not assert it, to repress the evil. If our freedom-loving American submits to the dictation of his tyrant and master as to trolley-cars, his master puts down the new tracks at night, with fiendish noises, and will by and by run the cars with the still more fiendish and ceaseless noises.

From whatever aspect the subject be considered it seems strange that people will submit to the indignities of the noise-makers. A thousand are outraged in order that one or a few may possibly be benefited. The shrieking of whistles and the ringing of bells to notify workmen to stop or to start work is an instance in point. Everybody has a watch or a clock at hand. Why, then, blow the whistles? Why, also, thunder or jangle bells to tell people that should be asleep what o'clock it is during the night? The 10 per cent. of people who go to church must be warned by bells; but have the 90 per cent. no rights who do not need or heed; and what about the sick? The milkman arouses a whole neighborhood in delivering a quart of milk. The cartmen, the peddlers, the hawkers, the ragmen, etc., bawl and howl to be heard half a mile away if some other greater noise near by did not drown their voices. There are persons that think it strange that barking dogs and crowing roosters in a city should be objected to.

All noises may be divided into the necessary, the partially necessary, and the wholly superfluous. The makers of the last class of noises should be proceeded against in the interests of the public health by all the forces and with all the vigor at the command of physicians. And this by all odds is the largest and most injurious class of noises. Here is a work ready for the Associations for the Public Good. There is something particularly exasperating and baneful in the unnecessary noise in the very fact of its unnecessariness. Let all the loafing rowdies, howlers, hawkers, whistle-blowers, bell-ringers, and the rest be incontinently hushed, and especially if they carry on their diabolism at night.

Concerning the class of partly preventable noises of cities, the greater amount of them is connected with street traffic, and here arises the shameful need of good smooth pavements. As with the strawberry, so it is with the asphalt pavement—doubtless a better one could have been or may be invented, but doubtless it never has been invented. It is incomprehensible that people should consent to endure the torment arising from the stone and boulder pavements, and seemingly designed, like African music, for creating the most intolerable clatter possible. In addition to this aspect of the question there is another reason why, as physicians, we should do away with block and cobble-stone pavement: they are excellent culture-grounds for lodging filth and disease-germs. The asphalt pavement offers no such a nidus and can be easily flushed and kept clean.

The degree and character of the civilization of a country are indicated by the amount of unnecessary noise it endures, and this is accurately gauged by the condition of the pavements of its cities.

THE PAN-AMERICAN MEDICAL CONGRESS.

DESPITE the fact that a large number of medical associations and societies have held their meetings within the past few months, an examination of the programs of the various sections of the Pan-American Medical Congress shows that the best papers have been held for the great gathering of the physicians of all America, to be held in Washington, September 5th, 6th, 7th, and 8th. It is evident that everyone who is not absolutely prevented will find it greatly to his advantage to attend. Patriotism unites with Medicine to make the event of extraordinary importance. The splendid programs give certain promise that the meeting is to be primarily scientific in character and that medicine is not to be an excuse for unlimited social diversion. The officers of the

Congress have long heroically labored to bring about the success that is now beyond all question assured. Let everyone determine to add the one thing that will make assurance doubly sure—that is, his daily presence at the meetings of the section of his choice.

EDITORIAL COMMENTS.

The Reform of Chemic Nomenclature must be gradual and moderate, and inconsistencies will have to be tolerated during the process; yet whenever a single step forward can be taken without risk, it should be taken. Thus the proposition to shorten *phosphorus* to *phosphor* might safely be adopted; and, despite its inconsistency, phosfor would be still better, even if the commendable change to fosfor have to be yet longer postponed. So, too, the terms *sulfic* acid and *sulfous* acid, *phosfic* acid and *phosfous* acid, are better than *sulphuric*, *phosphoric*, etc., and equally intelligible.

In addition to the shortening of chemic names, some approach to uniformity in the terminations of the names of similar substances is highly desirable. The recent multiplication of new products has in many cases destroyed a previously existing uniformity. Particularly is this so in the case of the *ins* and the *ines*. If the final *e* be dropped from the names of alkaloids, as seems advisable, the termination *in* should likewise be dropped from the names of all substances but alkaloids. In the case of one group of substances now bearing this termination, namely, the enzymes, an admirable substitute is at hand in *ase*, as now found in *diastase* and *invertase*. We should thus have *pepsase*, *trypsase*, *amylopsase*, *rennase*, and *steapsase*. In the case of substances now termed *metabolins*, *toxins*, and the like, the termination *it* or *a* could be employed; *anabolit* or *pneumotoxa* would be as euphonic and as manageable as *anabolin* or *pneumotoxin*. As to fanciful names of drugs, anti-(this)in and ex(that)in, their entire suppression would be no loss. Names somewhat indicative of chemic composition, and not too long for every-day use, can be found. In order to avoid confusion, however, the changes should be recommended by an authorized body, and we would suggest the appointment of a commission by the American Medical Association to take up the whole subject of chemic nomenclature in so far as it affects medicine (*i. e.*, physiology, pathology, and pharmacology), and to submit a well-considered scheme for shortening and rendering uniform the terms used.

Prostitution in India.—The British Parliament prohibited licensed prostitution in India, but the startling fact is out that the law remains a dead letter, and that the military authorities have continued to perpetuate the essential characteristics of the license system, on the ground that half-suppressed vice would be more harmful to the men than legalized prostitution. The *Woman's Herald* says that the investigation carried out by two American women proves that "the whole horrible system of regulation, registration, and compulsory examination of the unfortunate women is in full force," under the command of Lord Roberts and his officers. The *Indian Medical Gazette*, in the face of the sad and perplexing problem, claims that there is only one cure—marriage—and adds the following: "Recognizing the awful consequences of forced celibacy upon our soldiery, coupled with the debasing and wrecking results of its military substitute—licensed prostitution—physicians must boldly declare against the continuance of what is distinctly proved to be unsanitary and sinful. They must vote for what is healthful and right, and therefore ennobling physically, mentally, and morally. Remove the State provisions made for unbridled lust, and put in their place lawful marriage. If the upkeep of married soldiers and their families in India is costly, the cost of invaliding the hosts of venereal-stricken men is not a fraction less; it is probably more expensive."

We are by no means certain that this is best or that it is not best. The more profoundly and conscientiously one studies the problem, not only as to India, but as to every country and city, the more one is in distressing doubt as to what to advise. The purely sentimental view—that of women and of the Women's Christian Temperance Union—will certainly and more quickly lead to wretched depths of suffering and disaster than the license system, but ——.

The Infectious Nature of Acute Articular Rheumatism.—Analogy and the conceptions of modern pathology have long suggested an infectious origin for acute articular rheumatism, but the demonstration of such an etiology is yet wanting. An important contribution to this subject has just been made by Sahli (*Archiv für klin. Medicin*, Band li, Hefte 4 und 5, p. 451), of Berne, who, in a fatal case of acute articular rheumatism complicated by endocarditis, pericarditis, pleurisy, and pneumonia, succeeded in isolating from the affected joint, from the endocarditic vegetations, from the pericarditic and pleuritic deposits, from the enlarged bronchial glands, and from the blood, a microörganism corresponding in its morphologic characters with the staphylococcus pyogenes citreus, but not causing suppuration. Accepting the etiologic part played by this organism in the given case Sahli, raises the interesting question as to whether it is really a modified staphylococcus citreus or a distinct organism, himself leaning to the first view. The interesting proposition is also made that rheumatism may be caused by one of a number of organisms. In the case reported the evidence indicates that the endocardial, pericardial, and pleural inflammations were not true complications, but co-manifestations, with the joint-affection, of the localization of the causative agency of the primary disease.

The St. John Ambulance.—The Columbian Exposition, which is such an educator in many directions, is now able to exhibit a most admirable and complete ambulance service. The ambulance, which has just been secured through the energy of the head of the department, is a model for this country. It is the pattern well known in England as that of the St. John Ambulance Association. The strong, still-running wheels are surrounded by heavy rubber tires. The rear of the box opens by two doors, and a step comes down. A snap loosens a stretcher, which is drawn out on rollers; a second stretcher may be removed in the same manner.

When both stretchers are full, the first one is slid in on rollers and quickly raised on levers two and a half feet. The second stretcher is then run under it. Four injured men and two doctors can sit in the other half of the ambulance at the same time. The sides of the ambulance have each two large glass windows and curtains, with large manageable ventilators above the windows. The interior is lighted by electricity. This ambulance will easily and comfortably carry at one time the driver, two attendants, five injured persons sitting and two lying on stretchers. With this new ambulance the medical service at the Fair is complete.

A Scientific Investigation of the Poison of Rhus Toxicodendron Desirable.—THE NEWS of October 24, 1891, p. 484, and November 7, 1891, pp. 555. 556, contained a number of interesting communications concerning the toxic action of *rhus toxicodendron*, illustrating the remarkable property of this poison of transmission from person to person. Facts have lately come to our notice showing beyond question that the poison is often air-borne. There is a chance here for an interesting and valuable investigation to be made by some ambitious laboratory student or physician who has no personal idiosyncrasy as regards affection by the agent. The essential toxic principle should be isolated, its action on the human skin studied, and some therapeutic measure learned for the benefit of those poisoned. For certain persons the plant is harmless; to others it is a violent and persistent vesicant, the repetition and continuance of auto-infection by the affected serum being frequent, long, and violent. It is not impossible that the essential toxin might, under certain modifications, be proved to possess peculiar therapeutic power, and be a valuable addition to our materia medica.

Dying Declarations.—Physicians are frequently charged with dying declarations. The law governing their admissibility in evidence is well settled, says the Supreme Court of Alabama, in the case of Blackburn *v.* State, just reported (13 Southern Reporter, 274). Such declarations are not admissible unless they appear to have been made under a sense of certain and impending death. It is not what the court which passes upon their admissibility may believe the condition of the deceased was, for, although it may appear to the court, or to anyone capable of thinking rationally, that there was no possible hope of recovery, yet the question aside from that is, What was the state of the declarant's mind when the declarations were made? Did he appreciate the fatal character of his injury, and were his declarations uttered under the sense and solemnities of impending dissolution? If so, then, "when the death of the deceased is the subject of the charge, and the circumstances the subject of the dying declarations," they may be admitted in evidence; otherwise not.

Insanity from Jealousy or Revenge.—The heat of passion, and feeling produced by motives of anger, hatred, or revenge, is not insanity. The law holds the doer of the act, under such conditions, responsible for the crime, because a large share of homicides committed are occasioned by just such motives as these. If, however, there is any such thing as insanity produced by jealousy or revenge or wrath—genuine insanity, not mere turbulence of passion produced by desire for revenge; but if there is any genuine insanity, produced by any cause—then, says the Court of Appeals of New York, in the case of People *v.* Foy (34 Northeastern Reporter, 396), so far as affecting the prisoner, it is the same as any other kind of insanity.

REVIEWS.

DIE SYMPHYSEOTOMIE. Von PROF. DR. PAUL ZWEIFEL, Director der Universitäts-Frauenklinik in Leipzig. Nach einem in der medicinischen Gesellschaft zu Leipzig gehaltenen Vortrage. Leipzig, 1893.

SYMPHYSIOTOMY. By PROF. PAUL ZWEIFEL, M.D., Director of the University Obstetric Clinic, of Leipzig. A Report presented before the Medical Society of Leipzig, 1893. Small 8vo, pp. 79.

AFTER having had a remarkable success in the operation of Cesarean section, in which he has had as many as thirteen cases in order, with the loss of one child, but of no mother, Prof. Zweifel on September 27, 1892, took up that of symphysiotomy, since which date, up to April 27, 1893, a period of seven months, he had twelve operations without a death, and all of the children as far as reported were delivered alive. The first child died in two days; but nothing is said of a subsequent death in any of the other eleven. Prof. Zweifel, with his assistant, Dr. Döderlein, had eight Cesarean operations without a death last year; showing that he has made the pubic division a more frequent substitute for craniotomy. Of the twelve women, only one had the minimum *conjugata vera* of 2¾ inches, and the others varied from $3\frac{1}{16}$ to 3¼ inches. The children were in general of large size—from 19¼ inches to 21¾ inches long, and from 3200 to 3700 grams in weight; the bi-parietal diameters were from 3½ to 4 inches; the duration of labor was from seven to forty-eight hours, but only three extended beyond twenty-four hours. One woman had previously been subjected to the Cesarean section.

Case XII deserves special notice, as the woman, twenty-nine years old, had a double uterus and vagina, with the fetus developed in the right half of the organ. She had been eighteen hours in labor. The fetus was a male of medium size, born asphyxiated, but revived. The woman was 4 feet, $7\frac{5}{8}$ inches high, and had a generally contracted symmetric pelvis, with a conjugata diagonalis of 10.5 c.m.

Ten of the women were delivered by the forceps; the instruments of Tarnier and Naegeli being used; five by the high application, and four in the pelvic cavity, Prof. Zweifel having been very successful with symphysiotomy, as we have shown, is quite in favor of this method of delivery, which is now enduring the most severe trial that it has ever had to bear. It will require a test of several years before its true value can be established, as men are now divided in opinion, according to their measure of success, and this depends very much upon the care and patience exercised in drawing the fetus through the pelvis and soft parts. The chief danger is from sepsis, and this may come from the symphysis; or from lacerations made in delivery. There have now been thirty cases on this side of the Atlantic, with

four deaths: three operations in Canada, two in Brazil, and twenty-five in the United States.

Medical Pocket Atlases. Obstetrics. Part I, Labor, delineated in Ninety-eight Plates. By O. Schaeffer, M.D., Assistant at the University Frauenklinik in Munich. Translated and published under the supervision of J. Clifton Edgar, M.D., Adjunct Professor of Obstetrics in the University of the City of New York, etc. New York: L. Hydel, 1893.

In this small production the author attempts to depict in a series of ninety-eight colored plates the various fetal positions, normal and abnormal, together with the obstetric operations devised to correct the latter. As far as he goes he has been fairly successful in his aim, and most of the plates illustrate what they were intended to show. There are some grave defects, however, that cannot be overlooked. In the first place, the series of plates is by no means complete, and it cannot be claimed that "labor" has been fully delineated. The valuable dilating function of the bag of waters has been largely slurred; the *successive* stages of the various positions are not presented; the posterior brow-position is entirely omitted; the Schatz method of external version in face-presentation is but poorly depicted; the high position of the contraction-ring, the most serious complication in impacted shoulder-presentation, is not shown at all; and while the methods of version and the application of the forceps are presented, there are no illustrations of the several operations in embryotomy. Teaching by pictures is a valuable method of imparting knowledge, and the undoubted intrinsic value of this Atlas could be materially increased by an observance of the suggestions offered.

Sulla Origines dei Corpuscoli del Sangue. Ricerches del Dott. Vincenzio Allara. Milano: C. Chiesa e F. Guindani, 1893.

This new contribution to a study already rendered famous by Bizzozero, displays great boldness and originality of reasoning, with much interesting, though vague, research—vague, we mean, as regards the details, but explicit enough in other ways. The author proceeds critically rather than experimentally.

On the subject of the origin of the blood-corpuscles, his views may be summarized as follows: The white corpuscles arise from what he terms "mucous cells," or "cellule mucori." The "cellule mucori" are produced in the deep layer of the epithelium of the digestive canal, where they are held during their incubation (incubazione). The digestive canal (tubo digesente) preserves this function throughout embryonic and adult life.

Again, in the embryo tiny vesicles in the ciliated meshes that surround the vesicle of the allantois, which "now acquire a new significance, physiologically speaking, which is that from the epithelium therein arise the 'mucous cells' (or cellule mucore), and from these the large variety of the leukocytes of the blood and lymph. The origin of the white corpuscles of the blood and lymphatics is, therefore, not in the mesoderm, but, in truth, in the internal fold of the blastoderm.

We cordially recommend this book, which, in spite of some very obvious confusion, in spite of some lack of method, is a truly ingenious and original effort.

The Recrudescence of Leprosy and its Causation. A Popular Treatise. By William Tebb. 8vo, pp. 412. London: Sloan, Sonnenschein & Co., 1893.

The author, who has both travelled much in countries where leprosy is found and has read extensively the literature of the subject, calls attention in this volume to the danger of inoculation of this disease through vaccination. He is a strong opponent to vaccination, stating in the preface that "for nearly a century Jenner's prescription has been tried and found wanting." With this as the key-note to the book, the medical man knows what to expect in the succeeding pages. At the same time the subject is treated from a practical standpoint, the statements being supported by references from high authorities in this disease from all countries. Numerous cases and much evidence in favor of the author's theory, as well as on other points, are brought forward, with the conclusion that the disease is not contagious in the ordinary sense of this word; that it is inoculable; that the most frequent opportunities of inoculating the disease are found in vaccination, and that this is a true cause of the spread of the disease; that the increase of leprosy in the Sandwich Islands and elsewhere has followed *pari passu* with the introduction and extension of vaccination, and that there is great danger of extending the disease by arm-to-arm vaccination.

Electro-Therapeutics of Neurasthenia. By W. F. Robinson, M.D. (Physician's Leisure Library.) Detroit: George S. Davis, 1893.

The author, following Dana, adopts a clinical classification, making such divisions as neurasthenia of adolescence, climacteric neurasthenia, that following acute disease, nervous shock, etc. A decided preference is shown for the static current; twenty-two pages are devoted to it, sixteen to galvanism, and six to faradism. The author advocates large contact-electrodes for galvanism, moistened in a solution of sodium bicarbonate and for the abdomen a spongio-piline electrode, eight inches in diameter, instead of the small instruments so much in vogue.

In using faradism the author advises that the current be passed to the patient through the nurse's hand after a thorough soaking in warm water, with an attempt to get a massage effect in addition; but no directions are given for the use of a slowly interrupted faradic current for individual muscular contraction and exercise, one of the main-stays in the treatment of severe cases of neurasthenia. Dr. Robinson evidently studies and treats the patient as well as his disease.

Hypnotism, Mesmerism, and the New Witchcraft. By Ernest Hart. With twenty illustrations. New York: D. Appleton & Co., 1893.

Familiarity with the literature of the delusion variously known as hypnotism, mesmerism, witchcraft, etc. with thirty years' personal study of its phenomena, eminently fitted Mr. Hart for the investigation he undertook of the performances of Dr. Luys and Count Rochas. If

anything was needed to show how debasing all such experiments are, and to what extremes of imposture and immorality they may lead, these fearless papers have left that need no longer existant.

Mr. Hart shows clearly that the hypnotic state is an endowment of the subject, independently of the operator. But he shows, too, how the unfortunate subjects may become degraded into machines devoid of will, and what power the unscrupulous may gain over them. He has done a service not only to medicine but to sociology, to morality, and honesty.

We are glad that his papers have been gathered into book-form for permanent reference.

A CHAPTER ON CHOLERA FOR LAY READERS: History, Symptoms, Prevention, and Treatment of the Disease. By WALTER VOUGHT, Ph.B., M.D. Illustrated. 12mo, pp. 110. Philadelphia: The F. A. Davis Co., 1893.

THE lapse of time has fortunately almost dissipated the prognostication that "there is every reason to believe that cholera will appear this summer in our own country." Though a few cases have been brought to our doors, there is every reason to believe that our quarantine-measures will prevent the entrance of the disease. Dr. Vought has nevertheless succeeded in preparing a most interesting account of what there is worth knowing upon the subject. In successive sections he deals in a perspicuous manner with the history, the etiology, the epidemiology, the semeiology, the diagnosis, the prognosis, the treatment, and the prevention of cholera. While the work is dedicated to "lay readers," it will also prove valuable to medical men. It is thus deserving of a wide circulation.

REPORT OF THE COMMISSIONER OF EDUCATION FOR THE YEAR 1889–90. In two volumes. Washington, D. C.: Government Printing Office, 1893.

THE good results of such a work as this report can hardly be exaggerated. It is a mine of most valuable information to anyone interested in the subject of education of whatever kind and in all civilized countries. As regards medical education, the results of the report have already been epitomized by Dr. Bayard Holmes, of Chicago, in the *Journal of the American Medical Association*, January 14, 1893, a selection from which appeared in THE NEWS of February 18, 1893.

CORRESPONDENCE.

A LETTER FROM PROFESSOR CZERNY, OF HEIDELBERG.[1]

MY DEAR DR. C. H. MASTIN, Mobile, Alabama, U. S. A.:

I am truly ashamed that I gave you so much trouble, and that now the health of my wife and some unexpected troubles in the administration and arrangement of my clinic will interfere with my intention to visit the Congress at Washington, and to thank you personally for all your kindness, which you so richly bestowed to me during this year.

I must go with my wife to Kissengen, and I hope that she will be so much better that I can visit at the end of September the Congress at Rome.

You have been so kind to announce my arrival to many of the most prominent men in our science, and I must regret very much that it is impossible for me to use this opportunity to make the acquaintance of your great and interesting country, and the eminent members of the medical profession in America.

I hope that it will be possible for me to meet you in some more quiet year than this of the World's Fair, and that your kindness will pardon the troubles which I gave you by reason of the Pan-American Congress.

Some days ago I received the *Transactions and Minutes of the American Surgical Association*, and see that you are the Secretary of the Gross Monument Committee. Please let me enclose the little sum of $20 as a contribution to the monument, and express my admiration of the founder of the American Surgical Association and of the surgical work which he has done in your great country.

Believe me, dear colleague, the expression of the highest esteem of

Yours, very truly,

VINCENZ CZERNY.

HEIDELBERG, Aug. 1, 1893.

[1] [Through the courtesy of Dr. C. H. Mastin, of Mobile, we are permitted to publish this interesting personal letter.—ED. NEWS.]

FOREIGN BODY IN THE EAR FOR THIRTY-NINE YEARS.

To the Editor of THE MEDICAL NEWS,

SIR: In THE NEWS of August 5th, page 158, I noticed an account of a foreign body having been in the ear for twenty-one years.

On the 2d of April, Mrs. M., forty-four years old, came into my office complaining of a pain in the left ear, which, she said, had ached at times since she was a child. On examination I found that hearing was almost entirely lost in this ear and that the canal was filled with a hard substance. After considerable difficulty I dislodged a mass as large as an ordinary white bean, which in reality it proved to be, and which the woman recollected to have gotten in the ear when she was about five years of age, and which had thus remained there for thirty-nine years. Immediately after its removal she could hear the watch-tick at a distance of twenty inches from the ear, and since then she has had no trouble of any kind with the ear.

Respectfully,

W. F. CONNERS.

OIL CITY, PA.

NEWS ITEMS.

Pan-American Medical Congress.—Program of the Section on General Medicine: "The Principles of Immunity and Cure in the Infectious Diseases," by Victor C. Vaughan, of Ann Arbor; "Formas del Impaludismo," by Francisco A. Risquez, of Venezuela; "A Contribution to the Study of Prolonged Intermittent Fever," by David Lobo, of Venezuela; "A Study of Some Cases of Chronic Diabetes," by N. S. Davis, Jr., of Illinois; "Facts in Stethoscopic Percussion," by Henry Sewall, of Colorado;

"Typhoid," by W. C. Dabney, of Virginia; "The Importance of Eliminating Pelvic Diseases in General Diagnosis," by Mary H. McLean, of Missouri; "Colera Morbo Asiatico," by Santiago Hernandez, of Cuba; "Cholera: its Diagnosis, Prognosis, and Treatment," by J. M. Hurley, of California; "Cholera Asiatica," by J. D. Burch, of Texas; "A Case of Akromegalia in a Giantess," by Woods Hutchinson, of Iowa; "Cold Steel as an Anti-rheumatic," by W. K. Vance, of Tennessee; "Nutrition *vs.* Stimulation in the Treatment of Chronic Diseases," by W. H. Maxson, of California; "De la Buba," by Luis Razetti and N. Guardia, of Venezuela; "A New Disease of the West Indies," by Cuthbert Bowen, of Barbadoes; "La Cause de la Fièvre Jaune," by J. B. Lacerda, of Brazil; "The Bacteriology of Dengue Fever," by J. W. McLaughlin, of Texas; "Culture of Anaërobic Bacteria," by F. G. Novy, of Michigan; "A New Anaërobic Bacillus of Malignant Edema," by F. G. Novy, of Michigan; "Clinical Notes on Amebic Dysentery," by H. A. West, of Texas; "Some American Ideas about Chronic Diarrhea," by Ephraim Cutter, of New York; "Tratamiento Medico del Vomito Negro," by S. B. Mateo, of Cuba; "La Folie cher le Negre," by J. B. Lacerda, of Brazil; "Progressive Pernicious Anemia," by Judson Daland, of Pennsylvania; "Vasomotor Ataxia," by S. Solis-Cohen, of Pennsylvania; "The Value of Rest as a Therapeutic Agent in Chronic Pulmonary Tuberculosis," by Karl Von Ruck, of North Carolina; "Consideraciones Sobre dos Casos de Anemia por Ankylostoma Duodenale Observados en el Hospital del Victor Manuel de Lima," by J. B. Agnoli, of Peru; "Recent Experiences in Croupous Pneumonia, with Observations on Treatment by Subcutaneous Injections of Saline Solutions," by R. L. Cunningham, of Alabama; "On the Occurrence of a Form of Chronic Bright's Disease other than the Typical Fibroid Kidney, without Albuminuria," by D. D. Stewart, of Pennsylvania; "The Complicating Conditions, Associated Diseases, and Mortality Rate in Erysipelas," by James M. Anders, of Pennsylvania; "Carcinoma of the Bones, with Multiple Fracture; Ulcer of the Duodenum, with Death from Hemorrhage," by John H. Musser, of Pennsylvania; "The Anatomic Relations of the Plasmodium Malariæ in Pernicious Fever," by George Dock, of Michigan; "Filaria," by G. DeSaussure, of South Carolina; "The Nature of the Germicidal Constituent of Blood-serum," by Victor C. Vaughan, of Michigan; "Forced Respiration," by George F. Fell, of New York.

Papers have also been promised by Manuel Carmona, of Mexico; J. E. Graham, of Ontario; Dr. Guzman, of Nicaragua; Charles G. Stockton, of New York; F. Peyre Porcher, of South Carolina; C. S. Bond, of Indiana; I. N. Danforth, of Illinois; H. C. B. Alexander, of Illinois; E. L. Shurly, of Michigan; and W. S. Christopher, of Illinois.

The William F. Jenks Memorial Prize.—The third triennial prize, of five hundred dollars, under the deed of trust of Mrs. William F. Jenks, will be awarded to the author of the best essay on "Infant Mortality during Labor, and its Prevention."

The conditions annexed by the founder of this prize are, that the "prize or award must always be for some subject connected with obstetrics, or the diseases of women, or the diseases of children;" and that "the trustees, under this deed for the time being, can, in their discretion, publish the successful essay, or any paper written upon any subject for which they may offer a reward, provided the income in their hands may, in their judgment, be sufficient for that purpose, and the essay or paper be considered by them worthy of publication. If published, the distribution of said essay shall be entirely under the control of said trustees. In case they do not publish the said essay or paper, it shall be the property of the College of Physicians of Philadelphia."

The prize is open for competition to the whole world, but the essay must be the production of a single person.

The essay, which must be written in the English language, or if in a foreign language, accompanied by an English translation, should be sent to the College of Physicians of Philadelphia, Pennsylvania, U. S. A., before January 1, 1895, addressed to Horace Y. Evans, M.D., Chairman of the William F. Jenks Prize Committee.

Each essay must be typewritten, distinguished by a motto, and accompanied by a sealed envelop bearing the same motto and containing the name and address of the writer. No envelop will be opened except that which accompanies the successful essay.

The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year.

The committee reserves the right not to make an award if no essay submitted is considered worthy of the prize.

The Cholera.—The Imperial Board of Health of Berlin announces that there have been thus far this Summer only four cases of cholera in Germany. Three of the persons attacked died.

The official cholera report from the affected Russian governments for the week ending August 21 is as follows:

In Kiev there were 529 new cases and 184 deaths; in Nijni Novgorod, 468 new cases and 191 deaths; in the Don province, 245 new cases and 109 deaths; in Samara, 198 new cases and 75 deaths; in Kazan, 75 new cases and 28 deaths; in Kalisco, 97 new cases and 33 deaths; in Minsk, 32 new cases and 15 deaths; in Simbirsk, 31 new cases and 11 deaths, and in Kherson, 54 new cases and 22 deaths.

In the City of Moscow the daily averages for the week were 99 new cases and 38 deaths.

There have been five cholera deaths at Helsingfors, the capital of Finland.

From Bucharest it is stated that no cholera exists in that city. At Soolina the epidemic spreads rapidly. The mortality is exceptionally large.

There were on August 21 nine fresh cases of cholera in Naples, and six deaths. Seven fresh cases and five deaths were reported on August 22.

Deaths from cholera are reported from Oviglio, Roocaverano and San Giuliano-Vecchio.

Transportation Rates to the Pan-American Medical Congress have been obtained over most of the railroad routes to Washington at one and one-third the usual rate for the round trip, on the certificate plan. The Chairman of

the Committee is Dr. H. L. E. Johnson, No. 1400 L Street, N. W., Washington, D. C. The certificate referred to must be secured at the time of the purchase of the ticket to Washington, on which, properly signed by Dr. Johnson, the reduced rate will be allowed returning. The full fare is to be paid on the going trip to Washington, and a two-thirds reduction is allowed when the ticket is purchased in Washington for the return trip. These certificates must be obtained at the ticket offices at the time the ticket is purchased. Be sure to state that you are a delegate and will be in attendance at the meeting.

National Conference of State Medical, Examining, and Licensing Boards.—At a recent meeting of the National Conference of State Medical, Examining, and Licensing Boards held at Milwaukee, it was the expressed desire of the members present that all State Boards should be enrolled as members of the Conference, in order that future meetings shall prove of more than ordinary interest and profit, to the end of elevating the standard of medical education. It is also desirable that there be established closer relations between the various Boards, so that there may be an interchange of ideas and an active coöperation in all that pertains to higher medical education. The first annual fee is $2. Dr. C. K. Cole, President of the Board of Medical Examiners of Montana (Helena), is the Secretary and Treasurer of the National Conference.

Charcot Dead.—A cablegram from Paris announces that Jean Martin Charcot, the distinguished French physician, died on August 15th at Morvan.

Charcot was born in Paris in 1825. In 1856 he was appointed Physician to the Central Bureau, and from that time devoted himself to the study of the nervous system. His writings have been quite voluminous. He was a member of the Institute of France, of the Royal Irish Academy, of the Royal Medical and Chirurgical Society of London, and of many other scientific societies in various countries.

Dominion Medical Monthly is the name of a new medical monthly emanating from Toronto, Canada. The first number bears the date of July and contains a report of the third case of symphysiotomy recorded in Canada, in addition to an article on appendicitis, reports of societies, and other miscellaneous matter. The journal promises to be one for and by the medical profession. We question the wisdom of presenting reading matter and advertisements on the same pages.

Dr. John Guitéras, formerly Passed Assistant Surgeon Marine-Hospital Service, now Professor of Pathology in the University of Pennsylvania, has been appointed a Sanitary Inspector in the Marine-Hospital Service, and has been ordered by Supervising Surgeon-General Wyman to Brunswick, Ga., to assist in all preventive measures employed there.

THE AFTER-TREATMENT OF CATARACT-EXTRACTION.

BY WILLIAM OLIVER MOORE, M.D. (Columbia),
PROFESSOR OF DISEASES OF THE EYE AND EAR, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, NEW YORK.

ON the completion of the operation of extraction of a cataract, the cornea and the conjunctival cul-de-sac should be carefully washed with a warm boric-acid solution, in order that all secretions or coagula may be removed—a solution of mercuric chlorid, 1:8000, may also be used. The eyelids should then be gently closed, and over them placed a small square of old linen, either dry, or covered with oleum petrolei, cold cream, or the like. When the skin is delicate the oiled linen is preferable. Small pads of absorbent cotton are now gently placed over the linen cloths, sufficient in quantity to fill the space between the eyeball and the forehead, so that the pressure of the bandage will be uniform and gentle. This cotton may be medicated or not, as desired by the surgeon. Over this dressing is placed the roller bandage. This is made of fine baby-flannel, if in the winter season, and of cheese-cloth if in the summer. It should be from one and one-half to two inches wide, and about three yards in length, applied in the form of the well-known figure of 8. One begins on the cheek of the same side as the operated eye, then over this around the forehead, over the fellow-eye, and so on until the roller is finished. As a rule, only one pin is required to fasten the bandage, and this of the ordinary kind; I have never seen a bandage properly applied when *one pin* was not sufficient to hold it in position, except in the case of women having long hair. It is my custom in such cases, besides using the pin, as mentioned, to either fasten the bandage by means of a hairpin passed through it, and into the back hair, thus securing it, or put on an old-fashioned nightcap over the bandage, which keeps it firmly in place.

I am fully aware that all I have said as to the bandage is considered by many to-day as unnecessary and behind the times, and that we are only called upon to place bands of water-plaster, or any adhesive strap over the closed eyelids, and all will go well; this, we must admit, may happen; and I have also seen *one case* in which no dressing save a shade was required, and judging from the results, I should commend this plan of after-treatment, although we must all admit that the patient has far more comfort with the bandage. When the bandage is applied, the patient, if in the operating-chair or upon the table, should be gently led to bed, and when in it, allowed to assume any position that is comfortable and easy. The old practice of keeping cataract-patients in bed upon their back for the first twenty-four hours is cruel and uncalled for. The only caution necessary is that the eye be not struck by the patient's hands, the corner of the pillow, etc. The patient may have freedom in micturating, for great inconvenience and annoyance is often caused by the attendant insisting on the use of urinals, "ducks," etc. At the end of twenty-four hours, or earlier, if the patient is restless, a sitting posture may be assumed, the patient being dressed and allowed the use of an easy-chair. Many patients have done badly in the past, from the too rigid observance of the old ideas of after-treatment. Hypostatic congestion of the lungs may be set up by the rigid enforcement of rest on the back.

It is my custom to leave the bandage on both eyes for four days, without change, unless severe pain is experienced, when it is immediately removed; the eyelids are bathed gently with a solution of mercuric chlorid (1:10,000) in order to cleanse them; the lids should then be gently opened, and the affected eye inspected. When no pain occurs after the operation, and all is quiet at the end of four days, I remove the bandage *for the first time*, and inspect the eyes, first having washed them with the mercuric chlorid solution.

Of course, it is taken for granted that the room in which the patient is placed is moderately dark and has no sunlight falling in the apartment. I have, however, no sympathy with those who keep the room absolutely black—in fact, so dark that the blackness can "be felt." Such darkness not only injures the health of the patient, but is also a temptation for the attendants to keep the room untidy, thus favoring germ-development. It is to be hoped that these days will soon pass, and that instead of the *room being made dark*, the patient's eyes only shall be properly shielded during the healing process, by placing a fold of black silk or muslin over the applied bandage.

If, upon inspecting the eye, no undue redness is noticed, and if no evidences of iritis are present, a mydriatic need *not* be used, but should the pupil be

narrow, and the eye-ball quite red, then atropin sulfate, two grains to the ounce of water or oil, should be instilled twice daily. The bandage need not be applied over the unaffected eye after the fourth day, it being sufficient usually to simply shield it by means of a shade. On the eighth day I usually remove the bandage from the affected eye in the morning, and have the eye only shaded during the daytime, reapplying the bandage at night. London-smoke glasses are very useful as protectors, and with a shade over them give ample protection against the strongest light.

If the healing proceeds rightly, the patient may have the freedom of the floor upon which his room is located—that is, in walking to and fro for exercise—and at the end of four weeks he may have lenses adjusted, and go on with his usual life as before.

In an experience in the Mary Fletcher Hospital, at Burlington, Vermont, extending over a period of six years, the average duration of hospital-treatment was ten days, and in New York it has not exceeded fourteen. The shortest period of hospital-treatment was in a male, aged ninety-one, who remained in the hospital *three days*, when he was allowed to return to his home, with the wound thoroughly healed and the eyeball pale. This is one of the shortest periods on record. This patient was seen by my colleague, Dr. Roosa, who remarked that he should have thought three weeks to have elapsed, rather than three days.

In cases in which pain occurs, and in those in which on removing the dressings pus is found on the linen pad in considerable quantity, it can be safely concluded that purulent infection of the wound has taken place. This sign rarely fails. On opening the eyelids the corneal wound will be found infiltrated throughout its entire extent, and perchance pus will be found in the anterior chamber. In these cases the best treatment, and that which I adopt, is, after having carefully washed the eyelids with the mercuric chlorid solution, to cauterize the corneal wound throughout its entire length with the galvano-cautery, thus attempting the destruction of the infecting virus. Hot-water applications, made as hot as can be borne, used every two hours, ten minutes at a time, will greatly relieve the pain, and cut short the suppurative process. Atropin sulfate (gr. ij, aquæ ʒj) used every two hours, keeps the iris out of harm's way, and when combined with cocain greatly mitigates the pain. The reopening of the wound, and the removal by forceps of the exuded matter from the anterior chamber, are of no avail; nor is the injection of Panas' fluid into this space advisable, my experience having been against both of these procedures. The eye should be shielded from light in all such conditions. Purulent infection of the wound, and attendant suppurative iritis, usually result in closure of the pupil and a drawn-up iris—it may even go on to *panophthalmitis*, though this is rare.

The closure of the pupil as the result of this suppurative condition reduces vision to only perception of light. This is best treated by *iridotomy*, a few weeks after all the acute inflammation has subsided. *Iridotomy* may be performed by means of De Wecker's method—that is, by using the specially made stop-keratome, or iridotomy knife, which he has devised, and his iridotomy scissors. The scissors, or at least those that I have seen, are objectionable, in that being forceps-scissors they cut unevenly—that is to say, they bind well at the heel of the instrument, and not well at the extreme point, so that they bruise the iris rather than cut it, having given rise, in several cases seen, to irido-cyclitis. De Wecker's iridotomy may be made single or double, according as the iris is incised once or twice. The operation is done under cocain. The iridotomy knife is introduced in the same manner as for an iridectomy—that is, about one-fourth of an inch from the corneal margin, the instrument being held perpendicularly to the eyeball, and by gentle pressure forced into the corneal tissue and into the anterior chamber until the stop on the knife reaches the cornea, so that in this step of the operation the knife-blade is in the anterior chamber, in front of the iris and occluding membrane, and behind the cornea. The knife is now partially withdrawn, and then its point pushed through the iris tissue or membrane, making thus an opening for the subsequent introduction of the iridotomy scissors. The knife is then gently withdrawn, and the iridotomy scissors, with its blades closed, is introduced through the corneal incision (which is at the superior border) into the anterior chamber. One blade is then passed through the opening made in the iris tissue or membrane (or both), and the other blade being in front, the forceps blades of the scissors are pressed together and the tissue between the blades severed. If there is elasticity to the tissue a fair opening will be immediately noticed. Failing to obtain a sufficient pupil by one incision, the blades may again be placed in another position, and a second incision made, connecting with the first, forming an inverted V, or cordiform pupil. In some rare instances the parts cut will not retract, and we have to resort to removing a piece of the iris tissue. In treating these cases of closure of the pupil after purulent iritis and the like, I much prefer to use the much simpler method, iridotomy, with an ordinary cataract knife, as the procedure is so easy and there is less manipulation and danger in its performance.

The eye cocainized, with speculum and fixation-

forceps in position, securing the eyeball, a sharp, narrow Graefe cataract-knife is thrust through the cornea above and toward the peripheral portion, into the anterior chamber; the point is then thrust through the iris and membrane tissue into the vitreous chamber, and by a rapid downward cut the parts are divided, so that the resulting incision will fall opposite the corneal center as near as may be. The knife is now withdrawn, a small quantity of aqueous escaping, and the wound of entry closing immediately. This simple iridotomy is very effectual, and is to be highly commended.

Failure to secure a sufficient opening by means of the simple iridotomy at the first attempt, we may, after a fortnight, make a second endeavor, when we are likely to succeed.

The after-treatment to be adopted after either of the foregoing forms of iridotomy includes rest, a bandage, and the use of atropin sulfate (gr. ij to aq. ℥j), two drops four times a day—for one week. Usually at the end of this time any reaction that may have occurred will have subsided. As soon as the eye is quiet and all redness has disappeared lenses may be adjusted.

Prolapse of the iris is another accident to be spoken of in the after-treatment of cataract-patients. This is more especially liable to occur in those patients on whom no iridectomy has been performed, or after what is called the "simple operation." Even after the dressings have been adjusted, and during the interval between the operation and the first removal of the bandage this may take place, even in those patients in whom no prolapse occurred at the time of the extraction. This I have frequently seen in the practice of others (I prefer the compound operation); it has been probably caused by some undue exertion on the part of the patient, as coughing or sneezing, which has forced the iris through the unhealed wound.

When this condition is found, gentle efforts should be made to repose the iris into the anterior chamber by means of a spatula, but in my experience this rarely succeeds; eserin instillations are also very strongly advised, but again my experience is also against this method of treatment. Mydriatics and myotics do not act with any degree of satisfaction on the iris when the anterior chamber is leaking. When the iris cannot be replaced or reposed by means of the spatula, I should emphatically advise its excision by iridectomy. The treatment suggested by some, to allow the incarcerated iris to heal in the corneal wound, is, without question, dangerous. In those instances in which the iris becomes entangled in the angles of the corneal incision, when iridectomy has been performed, it is advisable to introduce the iris-forceps and free the entanglement by removing a piece of the iris-tissue. One should then carefully rub the iris back from the wound by means, *e. g.*, of a spoon, by pressure on the cornea over the point of the recent difficulty. This condition is exceedingly rare, if the precaution has been taken after the extraction, of carefully inspecting the wound before applying the dressings.

Prolapse of vitreous is occasionally found when the dressings are removed for the first time—sometimes appearing as a small bead in the center of the corneal incision, and again occupying the whole length of the wound. Healthy vitreous thus presenting in the wound acts as a foreign body and a wedge and prevents the healing of the parts. In the few cases that have come under observation I have found that a change from the former recumbent position and one of quiet repose to that of the erect posture and active exercise has done much to cause the vitreous to recede. By active exercise I mean walking to and fro in the ward or apartment with considerable freedom. Some advise cutting off the protruded vitreous by scissors, and then reapplying the bandage; some even advise introducing a delicate suture in the corneal wound. The first method suggested is preferable *every time*.

Entropion of the lower lid is occasionally the cause of much annoyance in the after-treatment of cataract, as the inverted lid causes irritation and conjunctivitis. The quickest way is to remove an elliptic portion of the skin of the lower lid and then unite the edges, thus producing shortening of the lid; many will not, however, submit to this. Straps of plaster may be placed close to the ciliary edge of the lid, and the lid drawn down by fastening the other extremity of the plaster on the cheek; this is unsatisfactory, as the tears soon cause the plaster to give way. Again, the lid may be held down by the finger and the patient directed to look up; while in this position an application of flexible collodion may be made to the skin of the lid parallel with the ciliary border, and the entire width of the lid. When the collodion is fixed the lid may be replaced, and usually this procedure will prevent the entropion for twelve hours, when the collodion band may be reapplied.

In some cases, in addition to these local measures, the administration of the fluid extract of conium internally has been of service. It seems to have an especial action on the muscles of the eyelids. It may be given in fifteen-drop doses every three or four hours, according to the effect produced.

Delirium after cataract-extraction has long been noticed and was thought by many at first to be due to atropin-poisoning; but this cannot be the fact, as it occurs in patients when no atropin or other drug has been used in the eye. It is not a surgical delirium, as the shock in the operation for cataract

is of no importance. It is probably due to the deprivation of light, and with patients of feeble physical or mental make-up. It not only occurs in those who have been operated upon for cataract, but has been noticed to occur in those confined to darkened chambers for other causes. Should this condition occur, it is evident, therefore, that the removal of the bandage and the use of a shade or colored spectacles are called for.

Striped keratitis is occasionally met with during the healing process, and may show itself in different degrees of intensity from a few bands to a complete opacity of the cornea. It is due to changes in the endothelial layer of the cornea produced by traumatism during the extraction. It usually clears up and the condition gives way in a few weeks; only rarely does a permanent opacity of the cornea remain.

Lachrymal diseases often coexist with senile cataract, and even in those cases in which the precaution has been taken to operate upon the diseased lachrymal passages before the cataract-extraction. Poisonous secretions are prone to linger and form beneath the closed eyelids. Some prefer to put a fine powder of iodoform along the line of the corneal wound; the only objection is the disagreeable odor. It is my habit in all such instances to remove the bandage after the second day, and not to replace it save at night, being satisfied to protect the eye from undue light by means of smoked glasses and a shade. By bathing and washing out the conjunctival cul-de-sac with mercuric chlorid solution, we are sure to prevent infection of the corneal wound by the infectious lachrymal secretions. In other words, these should be treated as open wounds.

Pain a few hours after the extraction of cataract is frequently noticed, and is to be expected in moderate degree, as the natural sensations of the parts are returning, and added to this is the sting and smart of the operation itself; if, however, the pain and discomfort do not speedily subside, it is wiser to remove the dressings, and very gently, without exposing the eye, pull down the lower lid of the operated eye a very little, just enough to allow any pent-up tears to make their escape. I have frequently seen this simple procedure give entire relief to the patient. The dressings should then be reapplied, and such cases may then go on favorably. Neglect to attend to such trifles will often protract the healing process.

Membranous or secondary cataract. In the majority of patients operated upon for the extraction of cataract, membranous or secondary cataract develops, varying in its appearance from a few weeks to several months after. So much so is this the case, that most operators explain to the patient before the extraction, the probable necessity of a secondary operation, or needling, that they may obtain the full acuteness of vision.

This secondary cataract, so called, is simply the thickening or wrinkling of the posterior capsule of the lens—with perhaps some portion of the lacerated anterior capsule curled upon itself. This membrane, being in the line of vision, of course reduces very materially the acuteness.

So long as we continue the present mode of extraction by lacerating the anterior capsule and leaving the capsular mass in the interior of the eye, we must expect membranous cataract. The ideal operation would be to remove the lens in its capsule; this has been done both by design and also by accident. However, as a plan of operating it has been generally abandoned.

In many the secondary cataract shows at the very outset, and even when the healing process is satisfactory. It can be seen best by an oblique light as a gray film stretched across the pupillary region, and by the ophthalmoscopic mirror appears as a cobweb-like material, wrinkled, and sometimes looking like watered silk, the reflex of the fundus showing through it. The density and opaqueness of the capsule cause more or less diminution of sight. Operations for membranous cataract should not be attempted until all signs of inflammation have disappeared from the eyeball, when needling may at any time be performed. The pupil should be fully dilated by a mydriatic, and the eye anesthetized by cocain. A speculum may be used for fixing the eyelids, or they may be held open by the fingers of the operator; some prefer the speculum and fixation forceps—in either instance the eyeball is fixed. A fine cataract-needle is taken and passed through the cornea perpendicularly to its surface, the point entering its tissue near the periphery, and then through and into the membrane, and then by a rotatory motion of the handle the point is made to make a rent in the cobweb-like substance. Care should be taken that no undue traction is made upon the ciliary region, as cyclitis may be set up by excessive manipulation. When the membrane is very delicate and thin, we can determine if the result has been accomplished by having an assistant concentrate light upon the cornea with a strong convex lens. If a sufficient opening has been made by the needle, it may be quickly withdrawn; the wound of entry is insignificant, and closes immediately on the withdrawal of the instrument.

When on the introduction of the needle into the membranous cataract the capsule moves with the needle without tearing, another, second, needle should be introduced on the opposite side of the cornea and the points of the two brought together and then gently separated, causing a rent; or one needle may remain fixed and the other one tear the

membrane in a direction away from it. This procedure will usually cause the most dense and tough membrane to give way.

Occasionally the opaque capsule will move to and fro in the pupil and cause the patient much annoyance, or the opening will get smaller. In such cases it is wise to do an extraction of the capsule, by making an incision at the upper border of the cornea with an iridectomy-knife, and then introduce into the anterior chamber a sharp hook, which is entangled in the membrane and then carefully withdrawn through the corneal incision; delicate scissors should then clip off the capsular mass. If the hook fails to bring the capsule into the wound, then delicate iris-forceps may be introduced into the anterior chamber and the capsule grasped by their blades, and then drawn into the corneal wound and excised by scissors. If the extraction was without iridectomy, care must be taken not to engage the instruments in the iris-tissue; if by chance the iris should prolapse, and it cannot be replaced by a spatula, it is best to excise it.

The treatment after either of these modes of discission, or extraction of the capsule, includes rest, a bandage for forty-eight hours, and atropin-instillations three or four times a day. If much pain results from these operations, the use of hot fomentations will usually give relief; if not, cocain may be added to the atropin solution.

Cystoid cicatrix occasionally occurs after extraction of cataract, especially if care has not been taken to have the angles of the wound free of iris-tissue at the time of the extraction; it may also occur in those when the healing process has been protracted, and thinning of the sclero-corneal junction has taken place in consequence. It is best to remedy this defect at once, for if neglected, it is likely to lead to irido-cyclitis. Iridectomy usually gives relief in these cases.

85 MADISON AVE.

THE DIFFERENTIAL DIAGNOSIS AND TREATMENT OF SUPPURATION OF THE ACCESSORY CAVITIES OF THE NOSE.

BY J. F. OAKS, M.D.,
OF CHICAGO, ILL.
FELLOW OF THE CHICAGO ACADEMY OF MEDICINE, INSTRUCTOR IN THE NOSE AND THROAT DEPARTMENT CHICAGO POLYCLINIC, ETC.

IT is the purpose of this paper to limit it to the more characteristic subjective and objective symptoms which enable us to differentiate between the affected areas and suppurative foci, together with a brief consideration of their surgical treatment.

Although it is only a comparatively short time since this subject has engaged the attention of rhinologists, yet our literature abounds with reports and communications on this subject, especially on empyema of the maxillary sinus, which latter has received the greater attention because it is more easily accessible and formerly was more often diagnosticated by accident. At the present time, while the recognition of suppurative disease of one or the other of the accessory cavities is comparatively an easy matter, the determination of the source of the purulent secretion or its focal point is often involved in considerable obscurity.

Most of the so-called characteristic symptoms are more or less common to disease of all of the accessory cavities, viz.: (*a*) Suppuration; (*b*) Neuroses, manifested by cephalalgia, neuralgia, and psychic phenomena; (*c*) Ocular disturbances.

a. SUPPURATION.—We have a purulent discharge (except in the latent form of the disease and when the normal outlet is obstructed) by way of the anterior and posterior nares, dependent upon concomitant obstructive lesions in the nasal fossæ involving the anterior or the posterior nasal openings; it is more or less periodic in its appearance, increased in the morning or on rising. The odor of the purulent discharge may be negative, or there may be a decided fetor, dependent upon some peculiarity of the pus, due to retention, decomposition, or admixture with retained secretions. We may have ozena, which term, to prevent confusion, should be restricted to fetor of the nasal secretions without specifying any particular pathologic condition.

Theoretically, the pus from the maxillary, frontal, and anterior ethmoidal sinuses should make its appearance in the middle meatus and nasal fossæ, but in the presence of an obstructive lesion involving the anterior end of the inferior turbinal, the direction of the purulent discharge would be toward the posterior nasal openings, and simulate disease of the posterior ethmoidal cells and sphenoidal sinus—the so-called Tornwaldt's disease.

Fränkel[1] has called attention to an increased flow of pus on placing the head well forward and downward for some moments as being characteristic of antral empyema. This sign cannot be regarded as a positive indication of the source of the purulent discharge, as it may occur in suppuration of the anterior ethmoidal cells, although, by preliminary cleansing of the middle meatus, and making the test in the morning, this would undoubtedly be quite a reliable differential sign: Pus from the ethmoidal and frontal sinuses is usually not so abundant as in antral empyema; furthermore, in ethmoidal suppuration, the quality of the pus is usually more inspissated and tends to caseation and the formation of crusts, which is seldom a feature in antral disease.

Posterior rhinoscopy often discloses caseous pus in the superior meatus, with maceration of the mucosa covering the middle turbinal, which is quite

characteristic of suppuration of the posterior ethmoidal and sphenoidal sinuses. A localization of the suppurating foci in this region is rarely possible by anterior rhinoscopy, while posterior rhinoscopy will often enable us to differentiate between involvement of the posterior ethmoidal and sphenoidal sinuses and the deep fissures of the pharyngeal tonsil.

b. NEUROSES.—Cephalalgia is one of the most constant of symptoms, and is common to all diseases of the accessory cavities when there is suppuration. According to Schäffer,[2] Killian,[3] and Grünwald,[4] it is quite impossible to diagnosticate the focus of the disease by localization of the headache. Grünwald claims to have seen frontal headache very common in antral disease, and comments on the absence of facial neuralgia in his cases, though most authorities consider this a characteristic sign of antral disease.

In disease of the frontal sinus there is usually supraorbital neuralgia, intermittent in character, and aggravated by mental effort and indulgence in alcoholic liquors. In ethmoidal disease we have orbital neuralgia, which may be deep-seated and diffuse, while in sphenoidal disease we may have deep-seated cephalalgia of a very distressing character, radiating through the side of the face and involving all the branches of the trigeminus, causing dental, infraorbital, and supraorbital neuralgia.

Rouge[5] cites a case in which a diagnosis of antral empyema was made on account of a severe infraorbital and dental neuralgia. The autopsy disclosed empyema of the sphenoidal sinus, with caries of the superior wall, perforation, and subdural abscess, while the maxillary sinus was perfectly healthy.

So constant is this symptom of headache in disease of the accessory sinuses that it is in every case advisable to carefully examine the nasal and accessory cavities, even if the patient deny any knowledge of intra-nasal disease—a fact well known to the clinician. It is very difficult, sometimes even impossible, to distinguish by subjective and objective study of a case whether the symptom in question be of a reflex nature or whether caused by focal irritation due to pressure from distention of the sinus-walls, either with or without rupture, or by inflammatory involvement of contiguous structures, caries, and necrosis.

Psychic symptoms are frequently encountered, as manifested by insomnia, mental hebetude or depression, even by melancholia with suicidal impulse. Grünwald[6] relates a case of bilateral empyema of the ethmoidal and sphenoidal sinuses in which there was but little complaint of headache; but the patient suffered from continuous pressure on the vertex, as if pressed upon by a hand, with inability to think or maintain a conversation on account of forgetfulness. This patient also labored under the delusion that he stood about ten feet away from the person in his immediate vicinity, and his own voice appeared as if coming from a distance. He was also affected with melancholia and periodic impulses to suicide.

c. OCULAR DISTURBANCES may be due to disease of any one or to a combination of diseases of two or more of the accessory cavities, caused by distention, a bulging of the sinus-walls into the orbital cavity, with or without rupture or discharge of purulent contents into the orbital cavity, and giving rise to exophthalmos, amblyopia, diplopia, strabismus, contraction of the visual field, etc. Although exophthalmos may occur in connection with orbital abscess, from rupture of the orbital walls of the adjacent sinuses, it is most frequent in ethmoidal suppuration, in which case the eyeball is usually crowded outward and well forward. When the source of the orbital abscess is the frontal sinus the eyeball is crowded outward rather than forward. On account of the proximity of the sphenoidal sinus to the optic foramen and sphenoidal fissure, we may have serious involvement of the optic nerves and motor nerves of the eyeball, with more or less impairment of vision as a result of pressure or inflammatory involvement of contiguous structures.

Berger[7] calls attention to a peculiar feature in connection with amblyopia, which he claims is diagnostic of disease of the sphenoidal sinus, namely, that the peripheral field of vision is invaded before the central field is affected. He would explain this by the fact that the central fibers of the optic nerve are distributed to the outer portions of the retina.

Let me in this connection call attention to the close interdependence of ocular disturbances and intra-nasal lesions, which fact would seem to make their associated study and treatment desirable and reasonable, and clinically of advantage to both patient and surgeon.

As, in a given case of suppurative disease of the nose or accessory cavities, the foregoing facts make it quite doubtful that we can determine with certainty the focus of suppuration, we are forced to resort to additional diagnostic aids, of which I will only notice, first, the probe; second, exploratory puncture, and third, translumination.

Jurasz[8] claims to have succeeded in determining the presence of pus in the frontal sinus by the use of the *probe*. Practically, it is a most difficult procedure, except when the normal opening has been enlarged by caries or necrosis. Grünwald[9] says that he has succeeded but once in many cases in successfully probing the infundibulum, but makes the encouraging statement that the ethmoidal and sphenoidal sinuses can be successfully explored. He places the utmost reliance on the probe in deter-

mining the focal point of disease in the ethmoid, and says that without the probe it is impossible to make a negative diagnosis, while with it we are enabled to examine all the hidden spaces of the middle and superior meatus. The distal end of the probe should be bent at an obtuse angle to explore the medial as well as the lateral and under surface of the ethmoidal turbinal. In ethmoidal caries or necrosis, on sounding with the probe the distal end will penetrate a small opening with roughened edges, and find itself in a cavity which is apparently smooth. This may be due to granulation-tissue covering carious bone, and can be determined by the use of a small curet of corresponding curvature. The normal muco-periosteum in this region is closely adherent and of sufficient firmness to resist the curet if used with delicacy. Not so, however, with granulation-tissue, which being less firm yields easily to the curet, and we are thus enabled to feel denuded bone. Another point that may prove of diagnostic importance is the fact that a carious spot is usually very sensitive to the probe and consequently quite painful, while the contrary is true when the muco-periosteum is healthy. Sounding of the sphenoidal sinus, although not so easy as that of the ethmoidal cells, is readily accomplished if one bears in mind the topography of the nasal fossæ. The probe is passed between the septum and the middle turbinal, forward and well upward, when it should be felt to enter through an opening into a space in which the distal end is freely movable. The success of the maneuver depends upon a tolerably straight septum and an absence of marked hyperplasia of the ethmoidal turbinal.

Exploratory Puncture.—In antral empyema there is but one sure and reliable diagnostic sign, viz., ocular demonstration of the existence of pus by *exploratory puncture*, with or without irrigation. In spite of the fact that the presence of lamina and septa more or less complete may give negative results when pus is pent up under such anomalous conditions, it, however, occurs so seldom that we may practically be assured of its absence. Zuckerkandl reported the result of 300 autopsies, in which he found incomplete septa in seven, and in only one was there found an accessory space, which, however, communicated with the main cavity by an opening of the size of a hemp-seed.

Translumination.—The method of electric illumination introduced by Voltolini, and variously modified, was until very recently regarded as an important diagnostic aid. Like many, it has proved only of complementary value. However, it is a procedure that is absolutely unobjectionable to the patient; has some value as a positive and very much more as a negative test, and is still in favor with rhinologists as a preliminary step to methods of exploratory puncture or surgical procedures.

The diagnostic value of translumination depends upon zones of illumination and shadows or umbræ. These are modified by anomalous conformation and thickness of the osseous walls and partitions, enlarged turbinals and pathologic conditions of the mucosa of the sinuses, with or without the presence of pus. Although translumination has proved a disappointment as well as an embarrassment to many, it is a useful aid, not only in the diagnosis, but also in the prognosis of antral and ethmoidal disease.

Of late I have followed the method of Renault[11] by placing an incandescent lamp of sufficient illuminating power in the mouth laterally, below the lower wall of the antrum (not centrally on the dorsum of the tongue as usually practised), when, under normal conditions, on each side, at the level of the nasal bones will be seen a clear zone of illumination, irregularly oval, less bright than the corresponding suborbital region, but clearly distinct from the surrounding darker parts. We also get an illumination of the pupil, known as the pupillary reflex of Davidsohn[12]. Garel[13] has called attention to a new sign, viz., "Absence of luminous perception on the affected side," which has proved of great value. According as the individual has a narrow nose, small maxillary sinuses, a high arched palate, or tumefaction of the turbinals, the value of the signs of Davidsohn and Garel are more or less vitiated. However, the presence of an umbra in the ethmoidal region, with a purulent discharge from the nose and translucency of the corresponding cheek, is a diagnostic sign of great value, and would point to disease of the ethmoid.

I wish incidentally to call attention to the fact that a dark-room is not absolutely necessary for successful experimentation with this method. A dark hood of any design, or a dark cloth, such as is used by the photographer, placed over the head of the patient and that of the observer, although not so esthetic as the dark-room, is quite as satisfactory.

It is in the cases of associated suppuration of two or more of the accessory cavities that we meet with the greatest difficulties in making a differential diagnosis, especially when this occurs on the same side.

It is necessary, therefore, to determine, first, the foci of suppuration, and second, whether they are primary or secondary infections. Killian[14] and Grünwald[15] report cases of associated empyema of the maxillary, frontal and ethmoidal sinuses with antral suppuration, in which the purulent discharge from the antral cavity persisted until free exit to the pus in the frontal and ethmoidal sinuses was established, which was followed by spontaneous cure of the antral empyema.

TREATMENT.—When ordinary treatment has failed to establish free exit for the secretions through the normal openings of the accessory sinuses into the nasal cavity, and the retention of secretion or the presence of pus has been determined or is strongly suspected, it becomes necessary to establish the patency of the normal openings by the probe, the air-douche, etc., or to create an artificial opening for the free exit of pus and to secure efficient drainage.

When disease occurs in connection with hypertrophy or hyperplasia of the turbinals, exostoses, polyps, other neoplasms, or carious teeth, it is of the first importance to remove these lesions as far as possible by the proper treatment, so as to permit of free access to the affected parts. I am of the opinion that the more radical and thorough surgical measures are far more gratifying in their results to both patient and surgeon than the tentative and too conservative treatment so often pursued. Suppuration of the accessory cavities runs a decidedly chronic course, and shows little tendency to spontaneous cure. While the disease is confined to the sinuses themselves there is no serious danger to life, but when it extends to the cranial or orbital cavities the prognosis becomes correspondingly grave. Therefore, the treatment must be not only curative or palliative, but prophylactic. In most cases of suppurative disease of the accessory cavities, the amelioration from proper surgical treatment is rapid, although the cure may be slow, owing to the chronicity of the disease and the extent of the involvement of contiguous structures.

From a critical analysis of the literature pertaining to this subject and clinical experience in a few cases which the limit of time forbids my reporting in detail, I have formulated the following conclusions:

1. When the presence of pus or the retention of secretions has been diagnosticated, the indications are to secure free exit of the same and efficient drainage.

2. In antral suppuration the opening should be made with chisel and mallet through the canine fossa, according to the method of Küster[17] or that of Robertson[18], and of sufficient size to permit exploration with the little finger and the small incandescent lamps; if necessary, this is to be followed by curettage and the dry method of Krause-Friedländer.[19]

3. In sphenoidal suppuration the method of Schäffer[20] is to be commended, viz., enlargement of the normal openings by breaking through the anterior wall of the sinus with the curet, and by thorough curettage.

4. In frontal suppuration the choice of operative procedure depends upon the indications: if there is bulging of the inner and upper wall of the orbit that site should be selected for the artificial opening. The point usually selected for the latent form is immediately below the superciliary ridge, and near the bridge of the nose; the opening should be of sufficient size to give free access to the sinus, for the purpose of exploration, thorough drainage, and reëstablishing communication with the nasal cavity.

5. In suppuration of the ethmoidal cells, guided by the indications of the probe as to the presence of caries and pus, we should proceed to open up all suppurative foci by means of the snare, hot or cold, the nasal cutting-forceps, the curet, trephine, gouge, or the galvano-cautery knife.

6. A thorough knowledge of the topography of the ethmoid, its anatomic relation to the cranial and orbital cavities, together with a high degree of manipulative dexterity, will enable one to proceed with the assurance and rapidity that is so desirable in view of the free and annoying hemorrhage that is usual in intra-nasal surgery.

705 VENETIAN BUILDING.

A SERIES OF WOOLS FOR THE READY DETECTION OF "COLOR-BLINDNESS."[1]

BY CHARLES A. OLIVER, M.D.,

ONE OF THE ATTENDING SURGEONS TO WILLS EYE HOSPITAL; ONE OF THE OPHTHALMIC SURGEONS TO THE PRESBYTERIAN HOSPITAL; CONSULTING OPHTHALMIC SURGEON TO ST. AGNES' HOSPITAL, PHILADELPHIA, ETC.

IT has long been known—ever since the time of Wilson—that of the three methods for the quick and ready determination of subnormal color-perception—direct comparison of pigment-colors, direct comparison of spectral colors, and the study of subjective after-color, complementary color—the first is the best, the most convenient, and

[1] Read before the meeting of the American Ophthalmological Society, held at New London, Conn., July, 1893.

the most accurate. The cheapest plan, and the one that is freest from error, is that of Holmgren (really Wilson), the candidate expressing his color-defect by the handling of a series of inexpensive wools. It is free from the objections of fixed tests, such as the color-tables of Daae, the yarn-covered spools of Schenkl, the pseudo-isochromatic wools of Donders, the embroidery patterns of Cohn, and the stick of Thomson. It avoids the errors of these plans, inherent in the fact that here the colors, which are mere arbitrary choices of the deviser, not only fail to express any definite percentages of lowered color-vision, and thus permit many candidates to escape by reason of the confusion-wool not being equal to the exact amount of the color-error, but also greatly curtail any choice to be taken by the candidate, by reason of the process of fixation upon tables, spools, sticks, etc. Further, it escapes the faults of a fixed method of nomenclature, as, for instance, the odd and even numbering in Thomson's stick, where the one salient point of the test is liable to become known, and the test thus rendered practically worthless.

To remedy these defects amongst the only proper and legitimate class of color-tests, I brought before this Society, in 1887, a series of loose wools, which were intended not only to avoid any mistakes that might arise from imperfect material as to color, dye, its character, and the choice of instrumentation, but to give to any instructed (even though lay) examiner a definite and intelligible grading of the exact amount and character of any lowering of the color-sense—a grading that could be compared and contrasted with any past or future examinations. and could be understood throughout the ophthalmic world.

To accomplish this purpose I made the following modifications of the Holmgren series:

I. Five individual tests were used—pure green, pure red, rose, pure blue, and pure yellow. In spite of any theoretic prejudices, the last two colors were added because they had served through a long individual experience as most useful tests in the detection of extremely slight and almost imperceptible color-changes.

II. Loose and separate skeins of wools were employed. This, the fundamental principle of the value of the Wilson and Holmgren method, can be well understood when it is considered that here no discoverable plan is given to the candidate—he merely having a mass of color-matches from which to take his own choice.

III. The colors were made of equal relative intensity. Here rests one of the greatest claims for the employment of this individual test. Nothing that is arbitrary was placed in the color-series. Each skein had a definitely related percentage of one or two of the principal test-colors, thus allowing the plan to resolve itself into the question of color-matching alone.

IV. The value of the color used in each test-skein was expressed. The unit of color, or equivalent, and its relation with every other skein in the test, was given by a system of metallic bangles which was made incomprehensible to all but the scientifically initiated.

V. The set was so constructed that it could be employed by any educated layman. This was accomplished by the system of nomenclature on the bangles, which, although unknown in their scientific value and signification by the lay-examiner in any case requiring such service, could be fully understood by any expert to whom the case was given for after-decision. This was done by reference to the key to the test accompanying each test. This method embraces the ingenious plan of Thomson. Should the case not necessitate such intermediacy, the expert examiner would know in a moment, by reference to his registry blank, the true value of the color-sense laid before him for examination.

VI. The test was so constructed that passing color-changes could be preserved and permanently kept for future comparison. This was done by the wool-naming, and was of value in furnishing means by which more accurate study of disease could be made, better notions of prognosis given, and more useful plans of therapy applied.

VII. The test was so constructed that written and verbal expressions of the character and the amount of subnormal color-perception could be given. This avoided the use of the vague terms designative of lowered color-perception, and placed the system of naming upon a sound and scientific basis, as in acuity of vision, range of accommodation, etc.

VIII. The wools were made of one grade of manufacture, and were dyed with vegetable material. This avoided any errors that might arise from supplemental use of touch, rendered the tints more lasting to light-exposure, and avoided any danger from detection of tint by odor of the employed dye.

IX. A black surface was used in testing. This was done so as to avoid as much as possible the simultaneous and successive contrasts that are so likely to form in irritated and degenerated visual organs.

After several years' trial I found that I could dispense with all but the five principal test-skeins, five pure match-skeins, and eighteen confusion-skeins of relative equal value to the pure match-skeins, thus reducing the test to an extremely simplified, though scientifically correct, process; which could be used at will in a few seconds' time by any educated

layman, or by the expert himself; a plan that was as sure to be understood in ophthalmic writings, and as certain in its answers of the ever-varying conditions of individual cases as any other methods of precision given to the scientific and busy physician.

For these reasons I have thought it well to introduce the new and simplified series,[1] believing that it is of practical advantage to every working ophthalmologist or ophthalmic expert in railway and marine service, and to every neurologist who finds it necessary to obtain a most delicate answer to the amount and degree of disturbance of sensory action in the visual apparatus.

CLINICAL MEMORANDA.

CLEFT PALATE, BOTH HARD AND SOFT, AND HARE-LIP.[2]

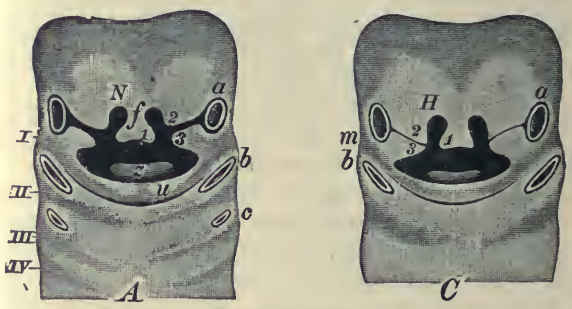
BY W. S. FORBES, M.D.,
OF PHILADELPHIA;
PROFESSOR OF ANATOMY, JEFFERSON MEDICAL COLLEGE, AND CLINICAL SURGEON TO JEFFERSON MEDICAL COLLEGE HOSPITAL.

THE affections named in the title are congenital. At the end of the third week in the development of a human fetus three deep pits, lined by a stratum of columnar epiblastic cells, appear on each side of the head, and, ultimately coming in contact with outgrowths from the developing brain, give rise to organs of special sense. One of these, the posterior, becomes the auditory vesicle; another, the middle, becomes the optic vesicle; and the third, the anterior one, placed near the median line, becomes the nasal vesicle. It is to this last that I wish to call attention.

The nasal vesicle, placed in front of the auditory and optic vesicles and close to the middle line, is connected by furrows with a deep invagination of epiblast, pushed in on the middle line, known as the stomodeum. At the fourth week of fetal life, the border of the head that forms the upper edge of the oral invagination below the anterior brain-vesicle, presents five marginal facial processes (Fig. 1, *A*.). The central one of these processes is the single fronto-nasal process (*f*, Fig. 1, *A*), which is separated on each side from the lateral nasal process (*2*, Fig. 1) by a nasal invagination. External to the lateral nasal process is the ocular invagination, at the outer and inferior border of which an outgrowth from the mandibular fold, the maxillary process, grows forward, separating the ocular invagination from the stomodeum. As it extends, its inner edge touches and coalesces with the outer side of the fronto-nasal process, making thereby a continuous upper lip for the aperture of the mouth. If from any cause the coalescence of the maxillary process with the fronto-nasal process is arrested and does not take place the deformity known as hare-lip is the result.

The union of the fronto-nasal and lateral nasal processes internally completes the edge of the anterior opening of the nostrils, while the thickening of these processes forms the nose. The lower edge of the oral invagination is made by the mandibular fold, which lies in front of the first visceral cleft, and in which the lower jaw, or mandible, is subsequently formed. These partitions between the nasal invagination and the mouth are at first superficial, but an ingrowing process from the maxillary process on each side eventually extends inward like a shelf to meet its fellow of the opposite side medially, thereby completing the roof of the mouth. At the same time the vertical septum, which grows down from above, separates the nasal fossæ and forms the nasal septum. The posterior extension of the middle nasal process, which takes part in the formation of the palate, becomes the premaxillary process.

FIG. 1.



Scheme of formation of the face and arrest of its development. (From LANDOIS.)

A, First appearance of the face; *I, II, III, IV*, the four visceral arches; *f*, fronto-nasal process; *N*, nasal orifice; *1*, inner; *2*, outer nasal process; *3*, superior maxillary process; *u*, inferior maxillary process; *b*, *c*, first and second visceral clefts; *a*, eye; *z*, tongue.

C, Arrest of the development, constituting oro-nasal cleft.

H, nasal orifice; *1*, inner, *2*, outer nasal process; *3*, superior maxillary process; *a*, eye.

Failure of union of the processes at the middle line taking place, or their development being arrested, the deformity known as cleft palate follows.

The failure of this median union of these processes may be partial or complete. Thus, the want of median union of the maxillary processes posteriorly only will produce a cleft of the soft palate; or a failure to unite may extend further, thus producing cleft in the hard as well as in the soft palate; or the failure in development may be complete and no union exist between the lateral nasal process of one side and the proximal surface of the fronto-nasal process, thereby producing a continuous cleft through the lip and through hard and soft palate. When the failure to develop is on both sides of the fronto-nasal process, then we have a double hare-lip and a V-shaped fissure through the vault of the mouth, and between the bifurcations of the V we find the undeveloped premaxillary nuclei, in which the incisor teeth are in time developed.

The failure in development and in attachment on both sides of the fronto-nasal process produces a hideous deformity. The patient I now bring before you presents such a condition.

C. A., a farmer's boy, nineteen years of age, coming

[1] E. B. Meyrowitz & Co., of 104 East Twenty-third Street, New York City, have kindly undertaken the manufacture of these tests, and have a most admirable, convenient, and cheap series ready for distribution.

[2] Read before the College of Physicians, Philadelphia, April 5, 1893.

from Virginia, presented himself to me in January, 1892; he was in reasonably good health; he had a double hare-lip, and a wide cleft in the soft and hard palate. The cleft bifurcated anteriorly, each bifurcation following the maxillo-premaxillary sutures. The vomer was greatly developed. The lower anterior marginal thickening coalesced with the premaxillary bones, which were pushed forward and upward. These parts were covered by a dense mass of vascular connective tissue.

FIG. 2.

FIG. 3.

The skin did not cover the anterior surface of the nasal septum, but projected forward, appearing like a well-developed nipple. There was an opening into each maxillary antrum. The entire lateral bony walls of the oro-nasal cavity were covered with a thick and very vascular integument, mucous membrane, connective tissue, and periosteum. The excessive vascularity in the whole field of operation was made very manifest in each operative procedure.

After several careful examinations, and after casts, diagrams, and photographs had been taken, I determined to first freshen the margin of the soft palate and then take lateral flaps containing periosteum from the lateral walls and suture these flaps together in the middle line as far forward as the maxillo-premaxillary sutures, leaving the treatment of the double hare-lip and the premaxillary bones and the greatly developed vomer for a future occasion. The antero-posterior diameter of the oral cavity was observed to be greater than usual. On the right side, the canine tooth, the two bicuspids, and two

FIG. 4.

FIG. 5.

molars were well developed, but they were placed in a straight line from before backward and outward. On the left side the second molar was absent, but the teeth on the left, like those on the right side, ranged in a straight line backward and outward, the two lines forming a V-shaped figure from before backward. The premaxillary bones, with the incisor teeth, were developed much in front of the apex of the V-shaped dental figure. Each half of the bifid uvula was larger than a normal uvula. The tensor palati and the levator palati muscles appeared to act with considerable force. The anterior pillars (palato-glossi) and the posterior pillars (palato-pharyngei) appeared to be subnormal.

A solution of cocaine was injected into the soft palate and into the parts covering the hard palate of each side of the fissure. The half-uvula of one side was seized with a long rat-tooth forceps and transfixed with a small double-edged, spear-shaped bistoury, and the incision carried up to a little nodule of bone, representing the undeveloped horizontal process of the palatine bone. A similar incision was then made upon the opposite side. Then, with a rectangular hoe-shaped knife, an incision was made along the lateral wall, and on a lateral ridge representing the undeveloped palatine process of the maxillary bone, and carried as far forward as the anterior edge of the nasal process of the maxillary bone and its juncture with the ala of the nose. The soft parts, including the periosteum, were brought down nearly to the margin of the alveolar process, thus leaving the flap attached by a large and broad pedicle. The same procedure was carried out on the opposite side. The hemorrhage was very considerable, but was arrested by ice and pressure. It required nine silver-wire sutures to hold the margins of these flaps in proper apposition in the middle line. The placing of the sutures was accomplished by means of a long needle with an eye at one end. This needle was thrust through the flap about one-quarter of an inch from its free margin and threaded from within, the wire being brought through the flap on the withdrawal of the needle; the needle then being thrust through the flap of the opposite side and threaded with the other end of the wire; then, withdrawing the needle, the wire was left in position. On drawing the edges of the flaps together a shot having a hole in it was run down the wire suture and compressed; the flaps were thus held well together. The making of the floor of the nose and the roof of the mouth was well accomplished by this procedure.

On washing out the nasal fossæ, none of the solution passed through the nasal floor to the mouth. The tension of the soft palate was now relieved by an incision on each side from above downward and obliquely outward, and at the same time from before backward diagonally through the soft palate. Pledgets of sterilized gauze were then placed in the nose and cotton over the middle facial zone. This completed the operation for the time and the patient was put to bed, and rectal alimentation was directed, with an anodyne.

After twenty-four hours had elapsed severe hemorrhage occurred, following a fit of coughing. After considerable difficulty this was arrestsd, and although the prostration was pronounced, the patient reacted rapidly.

On the fourth day three of the anterior sutures were removed and union was found to be complete. On the sixth day the three posterior sutures were removed and here union was also found to be complete. On the seventh day the remaining three sutures were taken out. It was found that one of them had cut out. It was from this spot that the bleeding had taken place. There was found to be an opening the size of a pea, where the suture had cut through. With the exception of this little opening, the union was perfect thoughout and the man was much improved. He went home in March. On his return, the last of January of this year, nearly ten months after the first operation, the parts were found to be well consolidated, and the small opening in the roof of his mouth had contracted a little.

While the fissure in the hard and soft palate was now closed, the facial deformity was still as great as ever. The second operation was performed early in February. Cocaine was injected into each lateral half of the lip. The parts were then dissected up from their attachment on each side to the maxillary bones, including the alæ

FIG. 6.

of the nose. It was found, however, that these flaps could not be made to cover the premaxillary bones; nor could these bones be forced back into the narrow cleft between the maxillary bones and into the narrow apex of the V-shaped figure already spoken of. With my bone-forceps the premaxillary bones and that portion of the vomer in front of the gap were removed. The anterior margin of the septum that I had made some months before was now freshened, and the canine teeth having been extracted, a rectangular flap from each side, having a broad pedicle carrying the periosteum, was raised and made to meet in the middle line in front of the lower angle of the vomer. These flaps were held to the vomer and in apposition to each other by animal sutures. The lip-flaps were now brought together in the middle line, and the parts were held in apposition by three steel pins.

The first pin was inserted into the cheek about a quarter of an inch external to the left ala nasi and passed nearly through the flap. It was then carried directly through the bony nasal septum and made to enter the right flap and reappear on the right cheek about a quarter of an inch external to the right ala nasi.

This pin held the flaps well together and in excellent apposition. A second and a third pin were properly passed through the lip-flaps. A well-sterilized silk ligature was now thrown around each individual pin in the manner of a figure-of 8, and a sterilized gauze dressing was placed over the naso-facial zone.

The pins were withdrawn on the fifth day, leaving the ligatures *in situ* for the time being. On the seventh day when all the dressing was removed, the parts were found entirely united. A fortnight after the operation a dental plate was adjusted, replacing the removed incisor teeth. A month after the last operation the man gave us the photograph which is here reproduced.

I am greatly indebted to Dr. Clarence A. Weaver, one of the resident physicians in Jefferson Medical College Hospital, for the photographs kindly furnished; and to Dr. E. I. Keffer for the preparation of the plaster cast from which one of the illustrations has been made.

1704 WALNUT STREET.

TWO CASES OF PNEUMONIA PRESENTING UNUSUAL FEATURES.[1]

BY LIEUT. A. E. BRADLEY,
ASSISTANT SURGEON, U. S. ARMY.

CASE I. *Pleuro-pneumonia of the lower lobe of the right lung, complicated with diaphragmatic empyema; convalescence established by expectoration of pus; cure complete.*—A. W., musician, Company C, Twelfth Infantry, after drinking heavily, was found lying in his bunk, apparently very ill, on the afternoon of March 10, 1893. Examination showed him to be in a semi-stupor from drink, and at the same time suffering severe pleuritic pain. He was at once removed to the hospital; the respirations were catching, jerky, and rapid; auscultation showed extensive friction-sounds over the base of the right lung, and faint crepitant râles; on percussion, a tympanitic quality of resonance was noted; tactile and vocal fremitus were apparently normal. The tongue was heavily coated. He was given 10 grains of calomel and 5 grains of soda, a broad bandage was firmly applied to the chest, and at night a hypodermatic injection of a quarter-grain of morphin was given. On the following morning his temperature had risen to 101.2°; the pain continued and the crepitant râles were more distinct. Three grains of quinin three times a day, and a stimulating, nourishing diet, were ordered. The evening temperature mounted to 101.8°.

On the following morning there was dulness on percussion over the whole lower lobe of the right lung, and rusty-colored, tenacious sputa caused much troublesome cough. Auscultation showed only faint, distant, bronchial breathing, but there was marked vocal and tactile fremitus. The tenacious mucus, no doubt, blocked the bronchial tubes and permitted little or no air to enter. In view of the coëxisting pleurisy, early recognized, the condition simulated to some extent a pleuritic effusion, but the fremitus pointed to little or no fluid in the pleural sac. The treatment was now ammonium carbonate, quinin, trincture of digitalis, and whiskey in such quantities and as frequently as the symptoms from time to time indicated.

On the morning of the 17th the temperature touched normal and convalescence seemed at hand, but physical examination still showed unsatisfactory conditions at the lower portion of the right chest. The chest-walls bulged, dulness on percussion existed, the respiratory sounds were distant, but there were no râles. It again seemed as if fluid were present, but exploratory punctures with hypodermatic and aspirating needles failed to give evidence of fluid. The general condition was excellent and the appetite good. On the 21st the temperature again began to indicate fever, and for the next two weeks it ranged from 100° to 103.2°. The presence of pus was suspected, and repeated attempts were made to locate it by means of exploratory punctures, but all failed. The line of percussion-dulness extended from the mid-axillary region forward and upward about 2½ inches above the normal line of liver-dulness.

During this period iodin was freely used locally, a supporting diet and internal medication carefully selected, and later on poultices were applied over the affected area. All attempts failed to locate pus, but the general condition and temperature pointed conclusively to infection at some point. It was concluded that a pocket existed in the diaphragmatic pleura, and, aside from occasional punctures in a vain attempt to withdraw or locate the pus, conservative treatment was adopted.

We were finally rewarded on April 7th, after a hectic condition of over two weeks, by the evacuation through the bronchi of the pus, which had so long been a source of trouble. During the first twenty-four hours no less than eight ounces were expectorated, but after this it appeared in ever-diminishing quantities, until finally, by the 15th of April, it was scarcely worthy of note, and had entirely ceased by the 20th. On April 7th the temperature was ranging from 99° to 102°, but from this time it steadily fell, and was normal when pus-expectoration ceased. During this period a supporting treatment was adopted, with local applications of iodin to the chest. Convalescence was rapid and uninterrupted. Before going to duty on May 11th the chest was given a careful examination, and, so far as could be determined, the cure was complete and no disability existed. The man went on six a months' furlough, and is at present visiting friends in Sweden.

This was without doubt a case of pneumonia-coccus, purulent pleurisy succeeding the attack of pneumonia. Some authorities state that there is reason to believe that in comparatively rare cases the pneumonia-coccus may reach the pleura through the lung, causing pleurisy, without inflaming the lung. Early in this case the most prominent features were symptoms of pleurisy; the pneumonia-cocci deposited in the pleural sac remained in a measure latent until defervescence showed the pulmonary inflammation to be at an end, when the germs assumed virulent activity, and in three days the symptoms gave unmistakable manifestations of pyogenia. Upon this subject there is an exceedingly interesting editorial article in the *Boston Medical and Surgical Journal*, May 25, 1893, vol. cxxviii, No. 21.

CASE II. *Pneumonia of the middle lobe of the righ lung; treatment by massive doses of digitalis for the first three days, which was then stopped; no cardiac effects were apparent until seven days after the first dose; digitalis-pulse for ten days; cure complete.* J. F. O., a private of Company B, Twelfth Infantry,

[1] Published by permission of the Surgeon-General, U. S. Army.

was admitted to hospital April 22, 1893, having had a chill the preceding day. Examination disclosed the usual symptoms of croupous pneumonia of the middle lobe of the right lung. The disease was confined entirely to this lobe, so far as could be determined by physical signs. During the first day the patient was given a mercurial purge and Dover's powder. On the following morning, May 23d, with his temperature 104.8°, the digitalis-treatment was instituted, in combination with chloral. He was ordered half an ounce of the infusion every hour, to be given until the temperature and respiration dropped to normal or nearly so. Chloral was given in 10-grain doses at intervals, to secure quiet and rest. Writers on this method of treatment uphold the fearless, bold administration of digitalis. In this case, after twenty-four doses, the temperature, on the morning of the 24th, had fallen to 101.8°. During this day the dose of digitalis was given every two hours. After twelve more doses the temperature at 8 A.M., the 25th, was 100°. The interval between doses was then increased to every three hours, and an evening temperature of 102.4° followed. On the 26th, at 8 A.M., the temperature had fallen to 99.2°, and the digitalis was stopped, and 5 grains of ammonium carbonate, a half-ounce of whiskey, and 3 grains of quinin were given three times daily.

With one exception to be noted, the convalescence was normal. During the time the digitalis was given the pulse was carefully watched, as being the indicator that would first announce a sufficiency of the drug. The pulse, during all the time the digitalis was exhibited and for three days after it had been stopped, presented no unusual features, not even a perceptible increase in tension. It is to be regretted that its frequency during these days was not recorded, but especial attention was paid to the pulse, and the first abnormal indication was discovered on April 26th, the morning of the crisis, and three days after the drug had been stopped. For several days the temperature was subnormal, as low at times as 97°, and from the 26th of April to the 7th of May the pulse was never more than 50 per minute, and was repeatedly found as slow as 36. It was really not until the 10th or the 11th of May that the normal frequency was established. During this period of subnormal temperature and pulse the condition of the patient was most encouraging; he seemed to be constantly improving, and suffered no ill-effects from the abnormal symptoms.

To epitomize: During the 23d, 24th, and 25th the patient took twenty-two ounces of infusion of digitalis; during these and the three subsequent days no effect on the pulse was apparent, though an undoubted effect was produced on the temperature.

On the morning of the 29th, three days after the exhibition of digitalis had been stopped, we had the characteristic slow, tense pulse of digitalis, and this persisted for ten days. To me this delayed and so-called cumulative action came as a considerable surprise, and for a time I was disinclined to ascribe the existing conditions to the drug employed.

In this connection I remember the case of a civilian teamster treated for pneumonia (not with digitalis) during the Pine Ridge troubles, in which the convalescence was marked by a persistent forty-per-minute pulse. In this instance the man claimed that this was his normal pulse-rate, but he insisted on leaving the hospital before his statement could be positively verified.

The patient in the case under consideration suffered no ill effects from the digitalis, except that after the second day it seemed to irritate his stomach and bowels, and it was for this reason that it was discontinued.

FORT SULLY, SOUTH DAKOTA.

TWO REMARKABLE CASES OF RECOVERY FROM POISONING—ONE BY OPIUM, THE OTHER BY CARBOLIC ACID.

BY ELIOT GORTON, M.D.,
ASSISTANT PHYSICIAN TO THE NEW JERSEY STATE HOSPITAL AT MORRIS PLAINS, N. J.

CASE I. OPIUM-POISONING.

ON the 13th of October, 1892, two of the male employés of the asylum, while on their way home from work, found a woman lying beside the road a short distance from the hospital, whom they recognized as one of our nurses. She seemed dazed and stupid, and as she could apparently neither walk nor talk, they carried her to the building, arriving at 6.30 P. M.

I saw the patient immediately, and found her in a semi-conscious condition, unable to stand or to talk coherently, although she moaned and cried out occasionally, as if in pain. Her pupils were strongly contracted, and this, in connection with the fact that I had treated her at different times for attacks of bilious colic, led me to believe that she had been overcome by one of these seizures, and, having resorted to opium in some form, had taken an overdose. In searching her, we found an almost empty bottle labeled "Laudanum."

The stomach-pump was used at once and the stomach found empty. However, apomorphin and brandy were administered hypodermatically, and the stomach was washed out with warm water. Retching occurred, but no vomiting. Strong coffee was then given, hypodermatic injections of brandy and one-thirtieth grain of atropin were administered freely, and the girl was forcibly held on her feet and kept moving. Flagellation with wet towels was also resorted to whenever the patient flagged, and as soon as those attending her were tired others took their places. At 10 P.M. these methods failed to be of use, and in spite of all efforts the patient became limp and unconscious. The face was cyanosed; the conjunctivæ injected; the pupils were the size of pin-points, and the respirations, which had been fairly good up to this time, fell to four per minute. The heart began to fail, and the extremities were cold. She was then placed in bed and twelve nurses, four at a time, relieved each other in applying massage. At 11 P.M. the respirations were three per minute, and the pulse, hardly perceptible at the wrist, was rapid and intermittent. Although we felt that we had a hopeless case to deal with, as a last resort the faradic battery was brought in operation, one electrode being placed at the diaphragm, the other over the phrenic nerve at the neck, with the result of increasing the respirations and relieving the heart for an hour, when this method became unsatisfactory, as the diaphragm failed to respond to the stimulation. At the suggestion of Dr. Prout, third assistant physician and pathologist, the electrodes were placed one over each phrenic nerve at the

point nearest to the surface where they pass in front of the scalenus anticus muscles, with a most gratifying and unlooked-for result. Respirations were increased or diminished at will, and immediately upon the contact of the electrode a full and forcible respiration occurred. At 1 A.M. the respirations had ceased entirely, except those produced by the strong electric current. The pupils were still contracted in spite of the one-thirtieth grain of atropin which had been given every half-hour since 10 P.M., and the patient was comatose. Dr. Prout and myself relieved each other at the battery every half-hour, and artificial respirations were kept up for six hours, or from 11 P.M. until 5 A.M., when our patient partly regained consciousness and the respiratory function became reëstablished. At the end of three days she was practically well, with the exception of an erythematous rash (probably due to the atropin) that covered her body and face, and which finally faded away. She stated that owing to some disagreement with her *fiancé*, she had taken the laudanum with suicidal intent.

The bottle bore the label of a firm well known to the profession for the purity and excellence of their preparations. She had taken ten drams of laudanum, U. S. P. strength, or the equivalent of five grains of morphin, as much if not more than that given to the unfortunate Helen Potts. It is my opinion that she owes her recovery to the massage and the battery, both of which were continued until she was out of danger.

The battery was a Jerome Kidder faradic, with Smee's cell, such as is figured and described in *Medical and Surgical Electricity*, by Beard and Rockwell, edition of 1883, p. 295.

I also desire to again call attention to the method of applying the electrodes, viz., one over each phrenic nerve at either side of the neck. There is no mention of such a method in any of our text-books which have come under my observation, nor have I ever seen any literature bearing upon their use in this manner. It certainly produced the desired effect, while the usual method of applying the electrodes to the nerve at the neck and the diaphragm failed. The normal number of respirations was produced for six hours consecutively, and the patient never failed to respond to the contact of the electrodes used in this manner.

CASE II. CARBOLIC ACID POISONING.

As if to illustrate the fact so often observed and commented upon by physicians, that one unusual case is commonly followed in a short time by another, on the 17th of October, or four days after the occurrence just detailed, at 7 A. M., it was reported to me that Mrs. S., a demented patient, had just taken a glassful of a carbolic acid solution. Bearing in mind the rapid diffusibility of this drug, no time was lost in getting to the ward with the necessary paraphernalia, and, though she was in a ward at the extreme end of the female department, probably not more than fifteen or twenty minutes elapsed from the time of taking the acid until active antidotal treatment was instituted.

The patient was found in a state of collapse, wholly unconscious, the pupils contracted, the face pallid, respirations short, shallow, and diminished in frequence, no pulse at the wrist and the heart-beats extremely intermittent and rapid. There would be several beats in rapid succession, then a pause of two seconds; then a single beat; then a few more beats and another pause, until it seemed that the heart would stop beating before any remedial measures could be applied. Apomorphin, one-sixth grain, and atropin, one-thirtieth grain, were given hypodermatically and the stomach-pump was used at once, though it was feared that the insertion of the tube would cut off breathing entirely. The stomach was thoroughly washed out with warm water, followed by the introduction of two quarts of water holding in solution four ounces of magnesium sulfate. At this time the apomorphin produced free emesis and the odor of the acid in the ejected fluid was very perceptible. Finally, two gallons of water in which a pound of magnesium sulfate had been dissolved were used as follows: the solution was pumped into the stomach until this became distended, when pressure upon it produced copious emesis; and this operation was continued until the circulation and respiration were restored and the patient regained consciousness. She was then put in bed, wrapped in flannel blankets, with bags of hot water to her feet and sides; a tablespoonful of brandy was given every hour, a tablespoonful of a saturated solution of magnesium sulfate every two hours until four doses had been taken, and the patient made a good recovery. Her throat was sore for several days, but, owing to the diluteness of the acid, no excoriation occurred. She swallowed eight ounces of a 2½ per cent. solution, or the equivalent of ninety-six grains of pure carbolic acid. This was not taken with suicidal intent. The nurse had been using the solution for disinfecting purposes, and inadvertently left the door of the wash-room open. The patient, desiring a drink of water, drank the glassful of the carbolic acid solution before the nurse noticed what she was doing.

No comments are necessary concerning these two cases. I consider the recoveries remarkable on account of the amount of poison ingested and the extreme gravity of the symptoms. They are illustrations of the results which can often be accomplished by the use of prompt, decisive, and continued measures, even when a case seems hopeless, and they also serve to emphasize the old adage: "While there is life there is hope."

For valuable and timely assistance in the management of the cases, I am indebted to the other members of the medical staff.

DEATH FROM NITROUS-OXID GAS.

BY FRANK J. THORNBURY, M.D.,
DEMONSTRATOR OF BACTERIOLOGY, UNIVERSITY OF BUFFALO, BUFFALO, NEW YORK.

NITROUS OXID (nitrogen monoxid, "laughing gas," protoxid of nitrogen) is a colorless, almost odorless gas, made by the distillation of ammonium nitrate at a temperature of from 460° to 480° F.

When pure nitrous-oxid gas is inhaled for from half a minute to three minutes, insensibility is produced, preceded in many instances by much excitement. Some persons under the influence of the gas sink quietly into unconsciousness, while others become hilarious, erotic, or pugnacious. During anesthesia from this agent, patients present evidence of asphyxia, although the phenomena of mechanical asphyxia are different from

those produced by nitrous-oxid gas. The cerebral pulsations are decidedly lessened and finally abolished, although the cerebral pressure is increased.

The causes of the effect of nitrous oxid upon the system are not positively understood; the phenomena produced seem to be due to deprivation of the blood of oxygen. One observer (Prof. Paul Bert), believing that the production or non-production of anesthesia by nitrous oxid is due to the tension of the gas in the blood, devised an apparatus by means of which the nitrous oxid could be administered to the patient mixed with an equal quantity of oxygen, under a pressure of at least two atmospheres; the result is said to be satisfactory. The method, although expensive and cumbersome, is much used in Paris. Smaller animals live in an atmosphere of nitrous-oxid gas for only short intervals, the time varying from thirty seconds for the mouse, to sixty minutes for the frog. All finally die of asphyxia. Life, however, can be sustained in the gas by introducing a quantity of oxygen, approximating that ordinarily contained in air.

The circulatory changes in asphyxia, due to deficient oxygenation of the blood, are at first peripheral. The dark, non-aërated blood refuses to circulate through the capillaries, and a damming back and subsequent paralysis of the heart take place. During nitrous-oxid narcosis the amount of carbon dioxid exhaled from the lungs is much below the normal. This anesthetic has been administered to hundreds of thousands of cases and but very few deaths are recorded. Only two or three fatal cases are mentioned in most of our standard text-books. The administration by means of an India-rubber bag containing at least eight gallons is the preferable method. The mouth-piece should contain two valves so that the expired gas is thrown out into the air and not back again into the bag.

Following this prelude to the use of nitrous oxid, I desire to make a brief report of an autopsy, made May 1st, for the Coroners of Erie county, upon a woman who died after the administration of four gallons of nitrous oxid by a dentist for the extraction of four teeth. Soon after the induction of anesthesia, the patient began to show signs of embarrassed breathing. Medical consultants were summoned. The pulse became rapid and attempts at breathing spasmodic. Artificial respiration was resorted to; the lower extremities were elevated. Nitro-glycerin, gr. $\frac{1}{100}$, was administered hypodermatically, and ammonia applied to the nostrils. The patient seemed to rally for a short time, but unconsciousness continued; the pulse became more rapid and feeble, and the heart's action finally ceased.

The report of the autopsy was as follows: The body is that of a middle-aged female, fairly developed and poorly nourished. Post-mortem rigidity is slight. Post-mortem staining is present over the pendant portions of the body. The ears are filled with cotton. The median incision shows the subcutaneous fat to be small in amount. No pleuritic adhesions exist in the thorax. The right lung weighs sixteen ounces, is universally congested and edematous; there is exudation of a large quantity of frothy serum. The left lung weighs thirteen and a half ounces, and is also congested and edematous. The lining membrane of the bronchi upon both sides are intensely hyperemic, and the tubes partially filled with frothy exudate. The heart weighs ten ounces and is of normal size and color. The ventricles are firmly contracted, and the walls of the left ventricle are slightly thickened. There is a dark clot in the chorda of the mitral valve. There are three minute atheromatous areas on the posterior wall of the aorta just above the segments of the valve. Over the anterior surface of the esophagus are two areas of hemorrhagic extravasation, irregular in outline and about the size of a half-dollar. The tracheal mucosa is heavily coated by a frothy, removable mucus. The larynx is congested and the lining membrane is also covered with frothy, slightly blood-tinged mucus. The congestion is especially marked in and just below the ventricles. The aryteno-epiglottidean folds are considerably corrugated, suggesting preëxisting edema. The position of the viscera is normal. The spleen is dark, moderately firm, normal in size and in consistency. The kidneys show a dark-bluish discoloration; the surface is smooth, the capsule non-adherent. The right is slightly smaller than the left, and contains a blood-clot beneath the mucosa of the pelvis and the true renal substance. This clot occupied an area one-half a square decimeter in extent. The ureters are normal and the bladder empty. No urine was obtained for analysis. The liver is normal, its weight three pounds. The stomach is normal in size and contains about six ounces of partially-digested food. The mucous membrane is coated with thick, semi-tenacious mucus; the membrane is slightly slate-colored in appearance. The intestines are normal. The uterus shows catarrhal endometritis, and there is a small quantity of mucus in its cavity. The left ovary shows a very recent corpus luteum and there is also a small cyst present. No adhesions exist. The right ovary and the tubes are normal. The brain was not examined owing to inability to obtain the consent of the Coroner.

This case illustrates the invariable presence of danger in the administration of anesthetics, even of the supposed harmless "laughing gas."

On the grounds of the pathology the use of oxygen in the treatment seems indicated, the condition of asphyxia, as shown, being due to the deprivation of the blood of oxygen.

MEDICAL PROGRESS.

Osteomalacia during Pregnancy; Porro Operation; New After-treatment.—SEELIGMAN (*Centralblatt für Gynäkologie*, 1893, No. 28, p. 649) has reported the case of a woman, thirty-seven years old, who, married for fifteen years, had been pregnant twelve times, seven children having been carried to term and five miscarriages having taken place. The hygienic surroundings of the family were ordinarily good. The children were usually kept at the breast for periods varying from ten months to two years, so that a new pregnancy took place before the preceding lactation was terminated. During the eighth pregnancy, which terminated in the birth of the fifth child, the woman began to complain of pain in the pelvic bones, extending thence to the upper and lower extremities and interfering with her ability to get about. Notwithstanding her deplorable condition, she conceived four times in the following seven years, bearing two living children and aborting twice. The last child was delivered by means of version and extraction, and

died soon after birth. The condition of the patient now became even worse than it had been. While dragging about upon crutches she fell and fractured the right thigh in its upper third. Shortly afterward the woman became pregnant for the eleventh time, and aborted at three months. She now fell into the hands of a so-called "wise woman," who applied one hundred leeches to different parts of the body, withdrawing a large amount of blood. Some time after this she became pregnant for the twelfth time. When seen, in about the thirty-fourth week of pregnancy, the woman was greatly emaciated and deformed. The right leg measured some two inches less than the left. The abdomen was prominent, and there existed a kyphoscoliosis dextra in the dorsal region and a decided lordosis in the lumbar region. The child occupied an oblique position in the pelvis, with the head to the right and the back anteriorly. The urine contained a trace of albumin, but no sugar. The distance between the iliac spines was 9.6 inches; between the iliac crests, 12.1; between the trochanters, 12.5. The external conjugate measured 7.4 inches. The pelvis, on examination, proved to be a typically osteomalacic one. The horizontal and descending rami of the pubes were approximated and the pubic arch presented a figure-of-8 shape, the sacral promontory projecting into the cavity of the pelvis. The symphysis projected forward and the diagonal conjugate measured 3.1 inches. The pelvic outlet just permitted the passage of two fingers. It was determined to perform celiotomy and remove the uterus and its appendages. As cholera was prevalent at the time, the operation had to be performed under unfavorable conditions at the woman's home. The woman suffered so much pain upon even the slightest manipulation that the preparatory bath had to be foregone. The operation was unattended with difficulty. The uterine stump was treated extra-peritoneally. Primary union took place without complication. The child also did well. As, according to the general consensus of opinion, it was to be expected that the pains would cease and the bones begin to become hard soon after the operation, it was decided to attempt to improve the woman's condition by extension of the whole body, and the results amply justified the attempt. At the end of eight weeks the size of the woman had actually been increased seven inches, and the right lower extremity was almost as long as the left. The configuration of the pelvis also underwent a change for the better. The diagonal conjugate was increased in size from 3.1 to 3.5 inches. The excessive spinal curvature was almost entirely overcome. From having been a helpless invalid the woman was able to resume her household duties.

Profound Cerebral Symptoms in Adults from Indigestion.—That profound cerebral symptoms may appear in adults, as well as in children, as the result of errors in diet, is well illustrated by two cases recorded by CORTIAL (*Archives de Méd. et de Pharm. Milit.*, 1893, p. No. 7, 56). One occurred in a man, twenty-three years old, who fell unconscious upon the street and was thought to have suffered a cerebral hemorrhage. About six ounces of blood were withdrawn and an ice-bag was applied to the head. All four members were agitated by movement, which was a little more marked upon the right than upon the left; the head was in constant motion; the eyes were turned upward and inward; the pupils were contracted; trismus was present; the pulse was rapid and regular; fever was moderate. The sphincters were continent; there was no hemiplegia. The stomach was distended and, notwithstanding the state of consciousness, pressure evidently induced pain. As cerebral hemorrhage is exceptional in young persons, alcoholism, indigestion, insolation, and heat-exhaustion were considered. The evidence pointed to indigestion as the cause of the symptoms and, accordingly, a further bleeding of ten ounces was practised; dessertspoonful doses of infusion of tea were administered; a purgative enema of senna was given; the epigastric region was gently cauterized; and massage of the abdomen was from time to time performed. In a short while the patient began to vomit, bringing up the remains of some salad taken the day before; copious stools also followed. Consciousness was only gradually resumed. It was, however, two weeks before the man was quite restored. He related that he had not been exposed to the sun or to intense heat, but that on the day before his attack he had partaken of some salad, and that on the day of the attack he had eaten nothing, on account of a severe headache and a feeling of malaise.

The second case occurred in a vigorous man, twenty-six years old, who was found unconscious, with eyes fixed; pupils contracted; respiration deep and a little stertorous; marked agitation of all four members, but especially upon the right, and without contracture; full but not rapid pulse; warm skin and hot head. He had been in good general health, suffering, however, with an attack of migraine about once a week. On three successive days there had been epistaxis. Stool had been painful and difficult. The man had gone to bed without making complaint, but toward midnight he was heard to groan, and then was found unconscious and in active convulsive movement. Other attacks occurred and were seen to be epileptiform in character. The parents asserted that the man had never had such attacks before. Indigestion being suspected, examination showed the abdomen to be distended and the percussion-note over the stomach to be dull. Strong pressure in the epigastrium appeared to induce pain and to excite a convulsion. After a bleeding of sixteen ounces the patient opened his eyes and became conscious. Abundant vomiting followed the ingestion of several cups of weak infusion of tea, bringing up imperfectly masticated meat. Purgatives were also administered, and in the course of a few days the patient was restored to his usual health. The distinguishing features of cases in which indigestion gives rise to cerebral symptoms are the fulness of the abdomen, with pain on deep pressure, and absence of modification of the respiration.

The Control of Hemorrhage from the Liver.—SMITS (*Geneesk. Tydschr. voor N. Indie*, B. xxxiii, H. 1; *Centralbl. f. Chirurgie*, No. 28, p. 622) has reported the case of a Malay, eighty years old, who was brought into the hospital apathetic and unconscious, presenting evidences of profound anemia. Below the ensiform cartilage and a short distance from the median line, on a level with the seventh and eighth ribs and parallel with the costal margin, there was an everted penetrating wound, about three and one-third inches long, from

which a steady stream of dark-red blood constantly flowed. There was no evidence of thoracic or abdominal complication. As the conditions indicated an injury of the liver, the outer wound was enlarged, and a wound a little more than an inch long and parallel with the external wound, was found in the liver, from which the dark-colored blood escaped. By means of a "mattress suture" the wound in the liver was readily closed with chromicized catgut, only so much of the blood-clots present being removed as interfered with accurate approximation. When it was seen that no further blood escaped from the liver the margins of the peritoneum were approximated with catgut and the skin-flaps with silk. Drainage was not deemed necessary. In addition, auto-transfusion was practised and stimulants were administered. The further course of the case was uneventful. The wound had healed at the end of eleven days, and in ten days more the patient was dismissed. In an ape upon which an aseptic celiotomy was performed it was possible to check the parenchymatous hemorrhage from the liver resulting from the excision of a wedge-shaped piece of tissue in the same way. The larger vessels were caught with forceps and ligated. It is thought that previous failures in suturing the liver may have been due to the fact that only healthy liver-tissue is suitable for this manipulation; a good result cannot be looked for if the liver be infiltrated, or syphilitic, or otherwise degenerated.

Generalized Melanotic Carcinoma.—LANDOWSKI (*Bull. de la Soc. Anat. de Paris*, tome vii, fasc. 15, p. 371) has reported the case of a woman, fifty-seven years old, who during life presented upon the skin in various situations small nodules of rapid evolution and of indubitably malignant character, death taking place amid the symptoms of cerebral hemorrhage. At the post-mortem examination nodules were also found in the pericardium, in the myocardium, in the kidneys, in the thyroid gland, and at the hilum of the lungs. The supra-renal capsules were greatly enlarged. There were small tumors in the mesentery, some of which, situated in the intestinal border, had ulcerated into the bowel. Tumors were also found in the course of all of the large vessels. The liver was intensely pigmented. Microscopically the new-growth presented the histologic appearances of melanotic carcinoma. The cerebral hemorrhage appeared to bear no relation to the carcinomatous diathesis, although the entire brain was dissected with great care.

To Sterilize New Cover-glasses ZETTNOW (*Centralbl. für Bakteriologie und Parasitenk.*, Bd. xiv, No. 2, 3, p. 63) has found it best, after having cleansed them, to place them upon a piece of sheet-iron, some three or four inches square, held for several minutes over the flame of a Bunsen burner. Thus treated, the glasses will not break. A dozen or fifteen can be sterilized in this way at one time. A copper plate will not answer, as the copper oxid developed by the heat would combine with the glass.

THERAPEUTIC NOTES.

Fatal Intoxication with Eucalyptus.—NEALE (*Australasian Medical Gazette*, April, 1893; *Practitioner*, No. 302, p. 129) has reported the case of a boy, ten years old, who took an ounce of oil of eucalyptus, and shortly afterward was found gasping for breath; he then vomited, with relief, and breathed well for an hour; but the struggle for breathing gradually returned and increased until death took place. Vomiting occurred but once, and there was no purging and no convulsion. The boy got out of bed, after vomiting, to take a drink of water; he spoke rationally up to within an hour of his death; and once he complained of pain in the right axillary region, which was relieved by a poultice. At the post-mortem examination the stomach was found greatly distended with gas. It contained a small amount of thick, yellow, odorless fluid. Its outer surface was white, except where it was stained by contact with the spleen; the inner surface was white, thickened, and puckered, as if painted with a mild solution of carbolic acid, but not brittle. The liver, kidneys, and spleen appeared healthy. The pleural cavities contained a quart of bloody serum. The lungs were compressed. The right heart contained frothy liquid blood; the left was empty and contracted. The brain was soft and pulpy; the membranes full of blood.

The Treatment of Erysipelas.—KOLACZEK (*Centralbl. für Chirurgie*, 1893, No. 28, p. 601) calls attention to the advantage of an occlusive dressing in the treatment of erysipelas, particularly as seen in surgical practice. For this purpose he employs what he designates as "rubber paper," which, at first, he moistened with a 5 per cent. solution of carbolic acid and had extend well beyond the margins of the affected surface. Latterly he has discarded the use of carbolic acid in this connection, as he found that it caused the paper to adhere to the skin to which it had been applied, so that its removal was attended with difficulty and distress. Over the dressing is placed a compress of cotton and a firm bandage. The dressing is changed after the lapse of twenty-four hours and a larger piece of rubber or additional strips are applied if the process has extended. The efficacy of the treatment is supposed to depend upon the suppression of the perspiration that results, the unexcreted metabolic products being thought to have a destructive or inhibitive action upon the streptococci. The success of the procedure depends upon the accuracy of the approximation of the dressing to the surface.

Salacetol is the name given by BOURGET (*La Semaine Médicale*, 1893, No. 41, p. 328) to a synthetic product consisting of 75 per cent. of salicylic acid and 25 per cent. of acetol. It is said to possess the intestinal antiseptic virtues of salol, without its disadvantages, and particularly its toxicity, which is dependent upon the carbolic acid that it contains. Given with castor oil, in the proportion of 30 or 45 grains to the ounce, it has proved useful in the treatment of summer diarrheas, choleriform affections, and cholera nostras. An adult may take the entire amount once daily, and repeat it if necessary. Children will take correspondingly smaller doses. Salacetol has also proved useful as a disinfectant for the genito-urinary tract, as well as in cases of subacute rheumatism and gout. The combination with castor oil increases its efficacy by inducing abundant secretion of the alkaline intestinal juices, thereby facilitating the decomposition of the drug.

SATURDAY, SEPTEMBER 2, 1893.

MEDICAL WRITING FOR ADVERTISING PURPOSES.

A DISTINCTION is readily made between medical writing, according as it is designed for the lay-press and lay-reader, or for the medical press and the professional reader. THE NEWS has contended that it is the duty of medical men to instruct the lay-world, through the lay-journal, concerning hygienic and medical truth. In so doing, however, there is great danger that the pure motive of public instruction may be debased by the alloy of self-seeking, and the writer descend to the moral level of the scamp who himself writes or suggests to the reportorial tool the "puffs" of himself, his goings and comings, his success in treatment, his appointments to positions, etc. All human acts are to be judged by the motive of the actor. Somehow or other the motive will become manifest. The self-advertiser loses delicacy of perception, tact, the little sense of modesty he ever possessed, and he more and more unconsciously sticks his cloven foot in the view of the whole world—that world that is growing ever more expert in the detection of Mephistophelean feet!

The medical writer in the professional journal is also to be judged by his motive, but his judges here, being his equals and more expert, more readily detect the ill-concealed marks of cunning and the secret desire to attract attention to the writer, while pretending to direct attention to the thing written. No one sees this unconscious display of motive so quickly as the pitiable (but never pitied) conscientious medical editor. This is partly owing to the fact that with him it is a matter of much experience, and partly also that it is his chief duty, in the interest of his readers, to thus discriminate between worthy and worthless writing. The advertiser, however, also often naïvely enough tells his own secret to the editor, for example, by insisting on the insertion of illustrations that do not illustrate, and that are designed simply to attract attention. The lay-newspapers are nowadays greatly exercised as to the insertion of cheap and worthless cuts, those journals which appeal to the most unintellectual readers finding it necessary to give the greatest number of worthless and untrue pictures.

It is a settled policy of the medical self-advertiser to write a certain number of books or articles each year, absolutely regardless of whether he has anything new to say, or whether what he says may be valuable or valueless to the profession. The editorial quandary is greatest in those rare cases in which the writer's motive is plainly selfish, as evidenced by the title, methods of expression, the insertion of egotistic and irrelative details, etc., but when also there is really something professionally instructive or interesting behind the tricksiness of conceit and advertisiness. Intellect and lack of principle are sometimes to be found in one individual, but the latter quality generally soon gets the upper hand.

When the medical advertiser writes an article for the lay-public for the purpose of attracting attention to himself, the fraud becomes manifest to his equals because the glitter of the born quack shines through every word. It is an appeal direct for patients. When he writes for the medical journals it is an appeal indirect for consultations and reference-cases. These appealers, therefore, are largely composed of professors and specialists, who want to "strike" the general physician or the specialists in other departments. It happens also that the ambitious use this means of calling attention to self simply to gain hospital-appointments, to secure professional positions, or to justify themselves before the world when such positions have been politically gained and the self-boomer knows himself that he has neither the requisite intellect, the adequate medical knowledge,

nor the clinical experience for such a position. Books and articles must be written to prove that the lie is not a lie.

And the writing of books and articles—what an easy matter for an expert! There are several methods:

There is, for example, the stolen patchwork method, which consists in cribbing from half a dozen or more authors or encyclopedias the data and ideas, so changed, of course, in language that no one can recognize the sources, and padded dextrously with assertions of personal experience, or with random bits of dogmatism, disagreements from the statements of this or that other writer, etc.—the whole thing not only medically valueless, but leading the trustful and ignorant into mistake and error.

Another common method is to hire for money or promise of preferment the brains of assistants and of those without practice, using the scholarship and the work of others as one's own. This has been a remarkably successful way in the past, but it is to be hoped that it is soon to become "stale, flat, and unprofitable."

Still another way is to build upon the apex of a cone of personal experience, used as a base, a very top-heavy superstructure of silly egotism and exaggeration. Last year, for instance, at a meeting of physicians in an Eastern city, an essayist, apparently to clinch a point as to the rarity of a certain pathologic condition, emphasized the fact that "in the one or two hundred beds under his care, and the three hundred and fifty dispensary cases daily seen by him," etc. Everyone smiled or sneered at the statement, knowing that it was introduced from no interest in the disease, but from much interest in the introducer. In two seconds everyone made the mental calculation that DR. HORNBLOWER saw something like a patient a minute for six or seven hours each day, or two patients a minute for three hours, and that the dispensary visits in that city numbered several millions annually.

Good medical writing is either a laborious digestion and epitomization of the medical experience of others, honest credit being given, or it is a concise setting forth in truthful, modest phrase of the sifted results of one's own clinical experience. Let us have more good medical writing for the sake of the profession and humanity, and less of sham medical writing for the sake of money-getting, thimble-rigging, and advertising!

APYRETIC INFECTIOUS ENDOCARDITIS.

A SHORT time ago (see THE NEWS, May 13, 1893, p. 521) we took occasion to advert to the occurrence of enteric fever without pyrexia. The obvious inference to be drawn from the admission of such an event is that other infectious processes may likewise pursue their course without elevation of temperature. As if in confirmation of such an assumption comes the report by SARDA and BOTHEZAT (*Nouveau Montpellier Médical*, 1893, No. 26, p. 511), of the case of a man in which, in the midst of an acute illness of ill-defined character, attended with anorexia, diarrhea, vertigo, headache, and insomnia, there developed gelatinous edema of the anterior thoracic wall, together with a systolic endocardial murmur heard over the left ventricle and not propagated. In the pulmonary area a duplication of the second sound was heard, which was attributed to a circumscribed dry pericarditis. Great weakness, with a typhoid state, supervened. In the course of the illness small quantities of albumin appeared in the urine, which was excreted in small amount and proved to be actively urotoxic. Examination of the blood disclosed the presence of diplococci. The patient became convalescent after the illness had existed for six weeks, and was lost to observation. There will, no doubt, be skeptics who, in the absence of post-mortem demonstration, will look with suspicion upon the accuracy of the diagnosis of infectious endocarditis made in this case, but it must be urged that there can be no substantial ground for such a position, as the competency and fidelity of the observers must be admitted, and as, besides, there is something in the *tout ensemble* of a case as seen at the bedside that cannot be reproduced in a clinical report. Granting, then, the accuracy of the observation, we are at once confronted with the difficulty of an explanation of the anomalous occurrence; for we know too little, as yet, of the temperature-regulating mechanism of the animal organism to adduce an explanation susceptible of demonstration. Speculating within what seem reasonable bounds, it may be that under certain conditions of infection toxic products are generated that do not act upon the heat-regulating mechanism in the same way as other toxic products usually do; so that in the one case we have an absence, in the other the presence of fever.

In further confirmation of the position here taken it is interesting to note that COMBEMALE (*Gaz. hebd.*

de Méd. et de Chir., 1893, No. 30, p. 352) has just reported two fatal cases of typhus fever, in both of which a transitory elevation of temperature was followed by persistent depression below the normal. He offers the alternative explanation of a toxic inhibition of the thermogenic centers in the brain or medulla, or the development of a toxic or infectious nephritis.

Finally, although we may not be able to give the explanation, it is well for the clinician, in fact it is incumbent upon him, to recognize that infectious processes may pursue their course and even lead to a fatal termination in the absence of all elevation of temperature; so that the absence of pyrexia need not be a bar to the diagnosis of an infectious disease.

"TO PREVENT THE SPREAD OF CONSUMPTION."

DR. DELANCEY ROCHESTER, a physician of Buffalo, N. Y., has adopted a method in preventive medicine and popular instruction that shows him to be a true-hearted and clear-headed physician. To the patient and to his friends in every case of pulmonary tuberculosis to which he is called he gives copies of a little printed slip, always carried in the pocket for the purpose, which reads as follows:

DIRECTIONS TO PREVENT THE SPREAD OF CONSUMPTION.

Consumption is an infectious disease, *i. e.*, it can be communicated to a person previously well by one who is suffering from the disease.

The agent of infection exists in the breath, to a limited degree, in the urine, the evacuations from the bowels, and the sweat in many cases, in whatever may be vomited, but *most of all* in the material that is *coughed up and spit out.*

As long as these materials are kept moist there is no danger of infection, unless they are brought into direct contact with the mouth, nose, eyes, or other mucous surface, or an open wound or scratch. If they dry on the clothing, on handkerchiefs, in a cup or spittoon, or other vessel, or on the floor or walls, they become disseminated through the air as minute particles of dust, and as such may be breathed in by a healthy individual, who thus runs the risk of infection.

Consequently, the underclothing and bedclothing of the consumptive should be changed at least twice a week (more often if the patient sweats much), and those articles of clothing taken off should be boiled for a half-hour before they are washed; the movements from the bowels should be passed into vessels containing water, and these vessels, as well as those into which the urine may be passed, should be thoroughly cleansed with boiling water; the sputum should never be expectorated into a handkerchief or other cloth upon which it might become dried, or upon the floor, walls, or sidewalk, but always into a cup or other suitable vessel containing water, which is kept covered when not in actual use; if the patient is walking about, a wide-mouthed bottle, containing some water and securely corked, can be carried in the pocket and used when necessary; the sputum thus collected should be emptied from the vessel three or four times in the twenty-four hours, and *immediately* burned; the vessel and its cover, or stopper, should each time be thoroughly cleansed with boiling water; the table utensils, including the napkin, of the patient should be thoroughly boiled before being otherwise washed; the mouth, nose, and throat of the patient should be thoroughly cleansed, at least twice daily, with a cleansing solution made by dissolving one teaspoonful of sodium bicarbonate (saleratus) in one-half pint of warm water. The well members of the family should not kiss the patient on the mouth; and under no circumstances should any one of them sleep in the same bed with the patient. The patient's room should be thoroughly ventilated and should never be tightly shut up; it should also be as sunny a room as possible.

We present this medical missionary tract in order to solicit suggestions of changes or additions that may seem wise on the part of our readers, and also to say that if a sufficient number of advance orders are forwarded to THE NEWS we will have a large number of the tracts printed at the cheapest rate possible, and will supply physicians with them at the inconsiderable cost of printing. We urge a hearty acceptance of the plan, as it is at once in the interest of true humanity and of a better understanding on the part of the community of the real spirit actuating the medical profession.

EDITORIAL COMMENTS.

The Association of Posterior Spinal Sclerosis and Exophthalmic Goiter.—Although exophthalmic goiter is far from being a rare disease, and although it has received a good deal of attention and study, both clinically and pathologically, there is as yet a lack of crystallized opinion as to its morbid anatomy. The lesions found in the fatal cases in which post-mortem examinations have been made have not been uniform, nor always significant; while the perfect recovery that takes place in some instances demonstrates that organic changes are not always present. It is just here that the pathologic classification of disease of the nervous system into functional, nutritional, structural, and organic, proposed by Gowers, finds appropriate application. Upon this basis it can be readily understood how in a disease like exophthalmic goiter, at first purely functional, nutritional changes may follow, and these in turn give rise to structural alterations, if the morbid tendency be not checked or eradicated. Thus it is that in some cases palpable changes are found after death, while in other cases no lesion is demonstrable. This conception will also shed some light upon the occasional association of exophthalmic goiter with other structural diseases of the nervous system, an association that is not to be looked upon as merely accidental, but dependent upon community of cause or community of predisposition. Records of cases

are not wanting in which exophthalmic goiter has been thus associated. For instance, THE NEWS of May 7, 1892, p. 520, contains a reference to a case of exophthalmic goiter, in which after death atrophy of the left restiform body and of the right solitary fasciculus was found; and THE NEWS of August 20, 1892, p. 214, contains the report of a case of exophthalmic goiter attended with incipient posterior spinal sclerosis. Recently MARIE and MARINESCO (*Revue Neurologique*, 1893, No. 10, p. 250; *Gaz. hebd. de Méd. et de Chir.*, 1893, No. 30, p. 354) report the case of a woman, thirty-six years old, who thirteen years previously had suffered with lightning-pains, followed successively by motor ataxia, laryngeal crises, diplopia, and gastric crises. Upon examination there was also found exophthalmos, with imperfect descent of the upper lid in association with the downward glance of the eye, tachycardia, and tremor, but without appreciable enlargement of the thyroid gland. There were present, besides, symptoms of posterior spinal sclerosis, with abolition of the knee-jerks. The woman died in an epileptiform crisis, and at the post-mortem examination, in addition to changes in the thyroid gland and the characteristic lesions of posterior spinal sclerosis, there was found symmetric sclerosis of the solitary fasciculus of the medulla and of the root of the trigeminal nerve. The opinion is further expressed that the bulbar theory of the etiology of exophthalmic goiter is the most reasonable.

Homeopathic and Faith-cure Statistics.—The *People's Health Journal*, a homeopathic journal of Chicago, publishes an exhaustive report of an exhaustive investigation by an exhausting homeopath, of the comparative statistics of homeopathy and "allopathy" as to the relative success in the chief American cities in the cure of disease. Of course, in every instance the poor "allopath" comes out with a sorry showing. The percentage of cures of the successful homeopaths should convince a doubting world, if figures could do it, and should make us hang our heads in bitter shame. Three simple facts, however, should be noted: 1. An attack of "spring fever" is not, by an honest man, diagnosticated as typhoid fever, nor every case of "sore-throat" classed as "diphtheria." Cure is easy and statistics cheap under such classification. 2. To have any value statistics must be gathered by impartial men, not by partisans. 3. No statistics exist, or by any stretch of sane imaginations can be supposed to exist, at the present time whereon to base such conclusions or any conclusions whatever. "Figgers won't lie, but figgerers will."

The homeopaths' half-sisters, the faith-curists, have also been holding a convention (conventions are fashionable nowadays), and had also their own splendid array of statistics. The *Boston Medical and Surgical Journal* says of these statistics:

"Out of two hundred cures reported, of thirty patients a diagnosis of organic disease had been made, and there were the usual number of fractures which had been marvellously reunited by faith. There was no record made, however, as to the subsequent position and deformity. The time of this method of cure appears to be much shorter than that required by surgical means—as one case of a broken ankle was said to have been cured in five minutes.

"The greatest curative effect of faith seemed to be upon erysipelas, for one hundred cases of speedy cures were reported. In what way the streptococcus is affected by a profession of faith was not clearly explained.

"The only case not curable by this means appeared to be rupture of the heart; for one person testified that by faith his child had been cured of colic, and a daughter of pneumonia. Their little one had been taken from them, but not by sickness; he died of a broken heart."

The Diagnostic Significance of Herpes Labialis.—Herpes of the lips is a symptom not uncommonly encountered in the course of an attack of cerebro-spinal meningitis and is considered of rather favorable omen in those cases in which it appears. It occurs much more commonly in the epidemic variety of meningeal inflammation than in the tuberculous variety. A series of observations by FELIX KLEMPERER (*Berliner klinische Wochenschrift*, 1893, No. 29, p. 693), at Strassburg, would seem to indicate that some degree of confidence can be placed upon the diagnostic significance of this phenomenon in the differentiation of these two forms of meningitis. He reports three cases in which, by reason of the family history and other attendant circumstances, there was reason to suspect the existence of tuberculous meningitis, but in two of which recovery presumably, and a post-mortem examination in one that terminated fatally actually, negatived such a diagnosis. Examination of the contents of the vesicles in two of these cases and in nineteen others disclosed the presence of pneumonia-cocci, staphylococci, and streptococci, respectively, in individual instances. The inference would thus seem reasonable that the organisms found may be looked upon as the cause of the formation of the vesicles, and the thought further suggests itself that they may be the same as those that are responsible for the primary affection with which the herpes happens to be associated. As herpes is of common occurrence in the course of diseases attended primarily or secondarily with the presence of micrococci, and is of rare occurrence in association with diseases dependent upon specific micro-organisms, it would seem that the appearance of the vesicles upon the lips may be considered among the points of discrimination in differentiating between the epidemic and the tuberculous form of cerebro-spinal meningitis.

Quackery and Lottery-gambling Join Hands.—In the *Christian Statesman* of July 29, Mr. Josiah W. Leeds gives a description of an advertising dodge devised by "The World's Dispensary" of Buffalo, N. Y. The scheme is so framed that it may possibly avoid the letter of the law, but if successful it is all the more nefarious. The Postmaster-General should look to it. It is proposed to distribute $10,000 in prizes among certain lucky holders of an advertising pamphlet of the *World's Expensary*. Mr. Leeds succeeded in arousing the manager of a general advertising company to a knowledge of the nature of the humbug, but could get no reply from the Chatham National Bank of New York, which seemed to be acting the part of bankers for the business. It is also to be gratefully noted that the *Christian Statesman* is *one* instance of a religious newspaper that will not admit the patent (which means, *not-patent*) mediciners to its ad-

vertising pages. The *Christian Standard*, the *Friend's Review*, and the *Christian Worker* are others, as we learn upon going to press. Is there another in the United States? If so, we wish to honor it!

The Oculist and the Trader.—A dealer in artificial eyes called upon an ophthalmic surgeon and said: "I came to thank you for sending me three of your patients, whom I have fitted with artificial eyes, and to give you the amount (five dollars for each case), as is my custom. . . . You will not take it? But Dr. Greatman, and Professor Expert, and Dr. Success do so—why should not you?"

The optician also called and introduced himself as a wholesale dealer, with the proposition to save the patient much money, and also to pay the physician 25 per cent. of the gross proceeds from the sale of spectacles. Again it was asserted that Dr. So-and-so, and that even such-and-such a hospital was pursuing this plan. It had, of course, never entered the mind of the trader that the manufacture and adjustment of spectacles is a science and an art, perfection in which requires years of study and experience, a conscience, and an intelligence begotten by no simple love of money, and he was, or pretended to be, equally unconscious of the perfect immorality of the proceeding.

Appendicitis in the Negro?—A valued contributor of THE NEWS, one of America's foremost surgeons, writes to ask if the negro is subject to appendicitis. He says:

"In common with other surgeons, I have had my share of cases, and have performed a number of operations, with a *very liberal* percentage of deaths; but I do not call to mind, nor can I learn of anyone of my Southern confrères who has seen the trouble in the black man. In days gone by, when I was in general medical practice and living in a population where there were large numbers of negroes, I do not think I have ever met, and I am certain I never recognized, a single case of disease in the region of the colon in the black man. This is a fact of which I have not seen any mention; and since the operation has been performed oftener at the North than at the South, it is questionable whether it has been thought of by any surgeon there."

We should be glad to record the results of experience in this connection.

Castration for Rape is not a new proposition, but, in view of the horrible prevalence of lynch-law in certain parts of the United States, it becomes a question if the procedure should not be given the sanction of good law-courts as well as that of the court presided over by the ferocious Judge Lynch. A correspondent in THE NEWS of April 30, 1892, proposes castration as a proper substitute for capital punishment. In such a suggestion there is no attempt to "make the punishment fit the crime," but for heinous sexual crimes castration would appear appropriate and logical. There is, however, a class of criminals, that will possibly be made more vindictive by any punishment, and especially by this form of it, and harbor a revenge perhaps more ineradicable than before against society. Then, too, a criminal thus punished has only to move to a part of the country where he is not known to escape knowledge of his mutilation. But, after all, the plan seems worthy of a trial.

The Mystery of Ice-Cream Poisoning is a reproach to the professions of medicine and chemistry. Year after year, with mournful reiteration, there are many reports of fatal cases. The deaths from this source must immensely exceed those from hydrophobia, but Pasteur institutes spring up like mushrooms in every country, whilst the deaths of the victims of poisoning by the cream are passed over in silence. Would it not be well to look into this matter? Would it not be well to prove or disprove the theory of a writer in THE NEWS (Dr. Hull, June 27, 1891) that the common ice-cream freezer is often an electric battery decomposing toxic products by means of the mixture acting as an electrolyte?

Increase of Lunacy.—The *Medical Press and Circular* suggests that the great increase of insanity (88,822 cases in England and Wales—2000 more cases than were on the list in January, 1892) may be accounted for by the law of supply and demand, the deficiency of asylum accommodation, etc., checking the increase, the waiting or preparing multitude ready to fill the increased accommodation. This is certainly calculated to give one the most decided "creeps."

"Honor to Whom Honor is Due."—In the *Medical Review* of August 5, 1893, there are nine distinct articles or abstracts taken from THE MEDICAL NEWS without a hint of credit. We are willing to forgive and forget on the ground that it was an oversight of the printer, that the editor was absent—on any excuse whatever, good or bad—if we could but have an opportunity.

The British Medical Association Has Admitted Women to Membership, by a resolution passed last year, and at the meeting this year made effectual by an amendment of the by-laws.

SELECTION.

THE GLAMOR OF SUCCESSFUL SURGERY.

I HAVE sometimes wished that, in the multiplicity of papers describing important operations and their great success, there might be an occasional one, not upon how to do, but upon how not to do it. There is a glamor about successful surgery—a flashing of swift fame, a glitter of gold and a promise of financial felicity, as well as the conscious pride of success and of instant relief—that may mislead, operations being done that might have been averted by judicious hygiene, and patient, wise medical treatment. It is useless to deny that unnecessary operations, sometimes sexual mutilations, are done, and that many women are saved from them by changing their professional adviser. Some are so blinded by their successful surgery that they are unwilling to admit that they have ever committed such a fault, and have no patience with those who suggest its possibility. Human judgment is fallible, and liability to error belongs to all.

I would not disparage the brilliant results obtained by abdominal section in pelvic suppurations, and I recognize among American operators many as able and as successful as any in the world; at the same time I would gladly see their work much more limited, as I believe it can be when medicine asserts its prophylactic and cura-

tive power, and it surely will in the progress of our knowledge.—PROFESSOR T. PARVIN, *President's Address, American Gynecological Society.*

REVIEWS.

SURGERY: A PRACTICAL TREATISE, WITH SPECIAL REFERENCE TO TREATMENT. By C. W. MANSELL-MOULLIN, M.A., M.D. Oxon., etc., Assisted by Various Writers on Special Subjects. With 600 illustrations, many of which are printed in colors, about 200 having been made from special drawings. Second American edition, revised and edited by JOHN B. HAMILTON, M.D., LL.D., etc. Octavo, pp. 1238. Philadelphia: P. Blakiston, Son & Co., 1893.

WHEN a work as large as this on a general subject, the literature of which is already so voluminous, comes to a second edition within two years, it would seem that the author has succeeded in impressing many readers with the idea that his teachings have some special value. Occasionally some department of surgery is undergoing rapid evolution, so that a frequent reissue of the books devoted to it is needful in order to keep pace with the progressive changes of opinion or of practice. Such, however, is certainly not the case with the volume now before us. It is almost identical with the first edition. The alterations that have been made are chiefly in arrangement, and are not always advantageous. For instance, it is not clear why Minor Surgery and Anesthetics should have been transferred from their former place, at the end of the book, to the portion treating of the General Pathology of Surgical Diseases.

Nothwithstanding occasional lapses into carelessness of style, this book is an agreeable one to read. But it is not, in our opinion, available as a guide to the practice of modern surgery. Neither the author nor the editor seems to have had clear ideas of what is needed in a work intended for this purpose. For example, the details of the antiseptic system are very vaguely set forth, and in a way calculated to make the reader doubt whether it has any real value. The various articles commonly used are enumerated, with brief comments, and then we find (on p. 166) the following:

"Hydronaphthol is strongly recommended as non-poisonous and as powerful as corrosive sublimate under the conditions of actual practice. It is very soluble in alcohol, but only slightly so in cold water. Salufer succeeds very well in the hands of some, and appears perfectly safe. Eucalyptus preparations are very agreeable at first, but patients are apt to get tired of the smell. Chlorid of zinc, which is stated to be almost inert as far as germs are concerned, is undoubtedly of very great value under special conditions." To this the editor adds: "Solutions of bromin and iodin have each an exceptional value in certain conditions."

These general statements teach nothing at all.

Again, on page 678, the editor says in a note: "Prof. Senn, in common with most German surgeons, prefers the chisel and mallet to the trephine." But we have been unable to find any directions given for the use of these instruments on the skull, and the student must seek this information, if he wants it, elsewhere.

In describing the operation of inguinal colotomy, the author says that, after the peritoneum is opened, "the finger is introduced and passed along the lower margin of the iliac crest until the mesentery guides it to the sigmoid flexure." Now, the fact is that some portion of intestine presents at once in the wound, and the surgeon has merely to make sure, by well-known anatomic features, that it is colon and not small intestine.

We note that there is no mention of hot water as a hemostatic; yet the value of this "wrinkle" is universally recognized at the present day. Again, in speaking of amputation, the author lays down as the first principle, "to sacrifice as little as possible." Modern surgery says—amputate at the point where the best stump can be made for the fitting of an artificial limb.

The editor has appended a chapter on "The Principles of Military Surgery"; but as it consists of only eleven pages, seven of which are devoted mainly to illustrations, this great subject is, of course, scarcely hinted at.

A number of new illustrations have been added in this edition; the bacteriologic ones, from Woodhead, are very good—most of the others very bad. None of them is sufficiently explained in the text. By way of frontispiece an exceedingly poor lithograph, purporting to represent Senn's operation of intestinal anastomosis, has been introduced. The portrait of Senn may be recognized; but the procedure is clearly an end-to-end suture, and the only visible instruments are four pairs of hemostatic forceps; the assistants seem to have fled. Figs. 193 and 205 would be more illustrative but for the fact that they are upside down.

We do not think that this volume is likely to add to the reputation either of the author or of the American editor. Should another edition be called for, it is to be hoped that the practical portion will be wholly rewritten, so as to bring it abreast of the times.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS, WITH ESPECIAL REFERENCE TO THE CLINICAL APPLICATION OF DRUGS. By JOHN V. SHOEMAKER, A.M., M.D. Second edition, revised. In two royal octavo volumes. Philadelphia: The F. A. Davis Company.

WHILE a good text-book on therapeutics and materia medica is ever acceptable because of the constantly changing character of the subject-matter, we cannot feel that Professor Shoemaker's volumes have contributed materially to our sum of knowledge of drugs and their applications. Not to mention the absence from the pages of original material, the numerous typographic errors, the incomplete indexing, the omission of diacritical marks from the Greek roots, and the want of uniformity in the spelling of words, all indicate a hasty preparation and imperfect proof-reading. The book gives one the impression of being rather a compilation than a scientific treatise on materia medica, and the entire absence of classification, as shown in an alphabetic arrangement of the drugs with the bare statement of results culled from an immense bibliographic source without discriminating deductions, is not conducive to a clear understanding of their actual therapeutic values. In numerous instances the most important properties of truly valuable drugs have been overlooked, while obsolete and worthless remedies, as onion and beet, have found full mention. Apiolene and oxalic acid, the two

most efficient emmenagogues at our disposal, have not been credited, while spermine and cactin are rather favorably treated, notwithstanding the worthlessness of the former and the uncertain composition and commercial character of the latter. These are but a few of many examples. As a compilation the book is a success, but as a text-book on one of the most fundamental branches of medical science it cannot hold a foremost place.

THE HEALTH-RESORTS OF EUROPE. A Medical Guide to the Mineral Springs; Climatic, Mountain, and Seaside Health-resorts, Milk, Whey, Grape, Earth, Mud, Sand, and Air Cures of Europe. By THOMAS LINN, M.D. With an Introduction by TITUS MUNSON COAN, M.D. 8vo, pp. 330. New York: D. Appleton & Co., 1893.

IN a brief, but very clever introduction, Dr. Coan points out the *raison d'être* for this little volume, which, while written for the invalid and the tourist, contains much information that will prove valuable to the physician who may wish to give intelligent advice upon the selection of a suitable climate, form of bath, or health-resort. It will be willingly conceded that a great deal can be accomplished by "natural" methods of treatment in a certain group of cases in which the never so skilfully combined drugs of the Pharmacopeia may prove entirely futile; but, as with drugs, the choice must be judicious and dictated by the requirements of the individual case. Dr. Linn has essayed a rather difficult task, which, however, he has performed thoroughly well. After some introductory remarks as to choice of place, time of departure, preliminary treatment, length of treatment proper, and other incidentals, a classification of mineral waters is given. Then follows a therapeutic index, but the bulk of the book is devoted to descriptions of health-resorts, with details as to routes, therapeutics, springs, physicians, hotels, etc. Finally there is a directory of physicians and an alphabetic index. The book is well printed, in large type, upon good paper, and can be cordially commended to any who may be interested in the subject with which it deals.

CORRESPONDENCE.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

To the Editor of THE MEDICAL NEWS,

SIR: Attention has recently been called to the presumed lamentable condition of the *Journal of the American Medical Association*, the slim circulation and poor literary and scientific quality of which are from time to time forced into trying contrast with the success, in each way, of the *British Medical Journal*.

Those who are uninformed of the exact situation in regard to the circulation of the *Journal* cannot judge absolutely of its state in this respect; but there is a general impression that it has few subscribers outside of those who may be regarded as in a sense forced to take it, for the reason that it is sent to all members of the Association who once attend a meeting and pay the fee of membership, until they default in payment or order it stopped. But of its literary and scientific attainments all who see may judge. In this we think an unbiased opinion would be that the *Journal* has never been a success. This we believe is due to several conditions: One is that the Trustees were, for some years, so selected that they should have no will, or should exercise none, except as this coincided with the will of the first editor, and that afterward the Trustees were so chosen that a handful of them could shape the policy of the *Journal* and control its finances, and that they did this in a manner contrary to the dictates of common sense, and wholly in a way to foster sentiments of local jealousy and suspicion at the expense of the true interests of the Association and of the medical profession of the country. More than this, in our judgment the editors of the *Journal* have, without exception, allowed the pressure of what they believed was pecuniary necessity to influence them to adopt, in the conduct of the advertising and reading pages of the *Journal*, methods which such a journal should never have adopted, and which were thoroughly disapproved of by many of those who ought to have been kept in sympathy with it. Another mistake in the conduct of the *Journal* has been, we think, in selecting editors who had no close relation with the medical writers of the oldest parts of the country. It happens in the world that there is a constant tendency for scientific work, while proceeding Westward, to keep its face toward the East, where the older mediums of communication between men of science and of letters are issued, and that literary productions go naturally and easily toward those older sections, while they go with difficulty away from them. This is the case as between the two hemispheres and as between the two principal halves of this one. Now, we think the literary success of the *Journal* will never be what it ought to be until it has an editor who is a man of real literary culture, and who is in touch with the best writers in all parts of the country and the world. Such a man, backed by a high-principled business manager, ought to be able to make the *Journal* of the Association a credit to the American medical profession; and there is no use in blinking the need for them both. To do so may minister to angered *amour propre*, but it will certainly carry the *Journal* and the Association still further in the retrograde direction which it has been taking for the past ten or fifteen years. Time and renewed meetings have removed some of the special causes of divided interest which prevailed in the American Medical Association when the *Journal* was a bantling, and it is supposable that the members of the Association are more likely to be governed by judgment instead of feeling now than they were when they stood on opposite sides of an important question. Those who sincerely desire the good of the Association may now recognize each other's sincerity of motive, and get together to make the Association and its *Journal* what they ought to be—strong and prosperous. There are in the Association enough men of honest purpose to defeat the schemers who are responsible for its present condition. To these honest men the *Journal*, properly managed, would be a most important factor in bringing about what is needed; but it must set an example of strict honesty, high principle, and intelligent management to attain this object.

These comments are suggested by a hearty wish for the good of the Association and its *Journal*, and the

fact that they are permitted to appear in the columns of THE MEDICAL NEWS is an evidence of the unselfishness of its editor and publishers; for if the *Journal of the American Medical Association* were well conducted and ably managed it would be the most serious rival to other American medical journals which could be imagined.

FIDELITAS.

DR. UNNA'S PLASTER-MULLS.

To the Editor of THE MEDICAL NEWS,

SIR: Those physicians who are interested in dermatology, and are consequently familiar with the reputation and works of the eminent specialist, DR. P. G. Unna, Director of the Heilanstalt fuer Hautkranke in Hamburg, will know that a favorite form with Dr. Unna for administering medicaments is the plaster-mulls. These plaster-mulls were originated by Dr. Unna, and have been used and favorably indorsed by many physicians, including such authorities as McCall Anderson, Janowsky, Robert M. Morrison, J. C. McGuire, Edward Brock, Chotzen, Bulkley, and others.

Plaster-mulls are an ideal improvement on the ordinary spread plasters; fine gauze is covered with the thinnest possible layer of gutta-percha, on which the medicament is evenly spread, properly dissolved in a minimum quantity of vehicle or base. The gutta-percha covers the skin-surface hermetically, prevents transpiration from the pores, and thus facilitates the deeper absorption of the medicament and enhances the specific therapeutic effect of the indicated remedy. The vehicle or base employed is non-irritant and a solvent of the remedy. Of the latter, an exact amount or dosage is added, and being perfectly dissolved, every particle of the ointment-surface will act equally; in other words, the plaster-mulls offer a sort of specific medication. A chief advantage besides this exact dosage is that the plaster-mulls are so thin, elastic, and pliable that they can be closely affixed to any portion of the body without cutting or patching. No artificial heat or other manipulation is necessary for applying these plaster-mulls; simply placing them on the surface requiring treatment, and holding them there for a moment suffices to firmly attach the plaster to the skin by virtue of the body-heat.

While these plaster-mulls have come into extensive use in Europe, they have not been generally adopted in this country, principally for the reason that they have not been manufactured here, and the importation from Hamburg was connected with difficulties, loss of time, etc. Recently, however, I have been enabled to procure a limited line of the most important medications of plaster-mulls, and I take early occasion to report my favorable opinion.

The medications which I have used are as follows: Salicylic acid, each roll one meter long, by 20 c.m. (about one yard long and eight inches wide), containing 10 grams, which amounts to about one-thirtieth of a grain of salicylic acid to the square inch of plaster-mull:

Mercury, 20 gm. ($\frac{1}{15}$ gr.).

Mercury, 20 gm. ($\frac{1}{15}$ gr.); with carbolic acid 7.5 gm. ($\frac{1}{40}$ gr.). Zinc oxid, 10 gm. ($\frac{1}{30}$ gr.).

Zinc oxid, 10, gm. ($\frac{1}{30}$ gr.); with tar 5 gm. ($\frac{1}{60}$ gr.). Ichthyol, 10 gm. ($\frac{1}{60}$ gr.).

Resorcin, 15 gm. ($\frac{1}{20}$ gr.).

Salicylic acid, 10 gm. ($\frac{1}{30}$ gr.); with creosote 20 gm. ($\frac{1}{15}$ gr.). Salicylic acid, 20 gm. ($\frac{1}{15}$ gr.); with creosote 40 gm. ($\frac{2}{15}$ gr.).

I have given up ointments almost entirely. They lack the neatness, elegance and efficacy of a well-fitting plaster-mull. The general physician will find plaster-mulls of great utility.

In my own practice I am now employing these plaster-mulls wherever indicated, and it is my intention in a subsequent communication to furnish some clinical records confirming the good opinion already formed.

HORATIO R. BIGELOW, M.D.

1716 CHESTNUT ST., PHILA.

ALBUMINURIA AND GLYCOSURIA FOLLOWING A SEVERE BURN.

To the Editor of THE MEDICAL NEWS,

SIR: A rare and sad accident recently occurred here. While burning stubble in her little farm of six acres, the clothing of a negress, forty-three years old, suddenly caught on fire. No one was nigh, and, after her loud cries for help brought some friends to her aid, she was immediately taken to her log-cabin, and I was at once sent for. I got to her house ten minutes after the accident.

I carefully examined her, and found her corpulent and seemingly robust body seriously burnt. The left hand was badly scorched, the skin shrivelled, and the abductor pollicis, opponens pollicis, flexor brevis pollicis, and adductor pollicis being quite shrunken and drawn, while over the trapezium, trapezoid, os magnum, and unciform bones there was a deep burn. The right leg was not less injured, the tibialis anticus, extensor proprius pollicis, extensor longus digitorum, gastrocnemius, soleus, plantaris, popliteus, flexor longus pollicis, flexor longus digitorum, tibialis posticus, peroneus longus, and peroneus brevis being quite shrivelled and flabby.

The sternum was injured, a severe burn, about the size of a gold dollar, being on the manubrium and the xiphoid respectively. The next part of the body injured was the vulva, the hair on the mons Veneris being badly scorched, and the clitoris, meatus urinarius, and glands of Bartholin; also, on physical examination, a few moist râles were heard over both lungs. The heart-sounds were feeble, lacking volume and clearness.

The patient complained of a deep sense of weight, as though one were bearing heavily on her diaphragm. She experienced a frequent desire to micturate. I found the urine of the normal specific gravity, but containing albumin and sugar in small quantities. Speech was feeble and not well articulated. The treatment I employed was a dressing of oleum amygdali on young fig-leaves. In addition a combination of morphin with cherry-laurel water, tincture of gelseminum, and tincture of hyoscyamus was given every four hours.

The accident occurred at 11 A.M., and the patient died on the next day at 9.30 A.M.

Your obedient servant,

HENRY HARTLEY, M.D.,
Medical Mission Priest.

OGEECHEE, CHATHAM COUNTY, GA.

ANOTHER CASE OF PRECOCIOUS PREGNANCY.

To the Editor of THE MEDICAL NEWS,

SIR: In September, 1888, I was called to see a colored girl in my neighborhood who was said to be suffering

with dropsy. An examination revealed, to my astonishment, a seven months' pregnancy. This child, then several months less than thirteen years of age, was only fairly well grown for her age, and was totally undeveloped, to all appearances. There was absolutely no growth of hair upon the mons Veneris and no development of the mammary glands. I was positively assured that she had never menstruated.

On the 11th of November I attended her in confinement, and, after a comparatively easy labor, the second stage of which lasted rather less two hours, she was delivered of a vigorous female child, weighing about five and a half pounds. The action and ability of nature in moulding the head in conformity with the capacity of the pelvis was more beautifully exemplified in this case than I have ever seen it in another. The mother and child did well. The father, by the way, was a very large negro of at least fifty years of age, and the husband of a great-aunt with whom the girl lived.

Very truly yours,

R. M. SLAUGHTER, M.D.

THEOLOGICAL SEMINARY, VA.

A.; Exhibition of a Field Hospital Complete with Equipment now in use in the U. S. Army; "First Aid to the Wounded and Transportation of the Wounded from the Battlefield and Field Hospitals;" Visit to the Army Medical Museum: (*a*) Inspection of Collection; (*b*) Inspection of Library of the Surgeon-General's Office; "Amputations Prothetically Considered," by George E. Marks, A.M., New York; "The Laws of Growth of Bacteria applied to Antiseptic Surgery," by Robert Reyburn, M.D., Washington; "Wounds of the Mannlicher Rifle in the Recent Civil War in Chile," by A. M. Fernandez Ybarra, A.B., M.D., New York.

The Cholera.—Two cases of cholera were reported in Rotterdam, on August 24th, and nine cases on August 25th. One new case and two deaths were reported on August 29th. Isolated cases were reported elsewhere in the Netherlands.

The reports concerning the progress of the disease in the infected districts of Austria and Hungary are contradictory. One death in Vienna has been reported. The infection was ascribed to drinking the unfiltered water of the Danube. One death is also reported at Althafen, a suburb of Buda-Pesth. The official returns from Galicia show that forty-two new cases and twenty-eight deaths were recorded on August 26th and 27th. On August 28th 134 new cases and 78 deaths were reported in Hungary. New cases are reported from time to time from Antwerp.

From Berlin it is reported that but for a few sporadic cases, traced to outside sources, Germany is still regarded as free from cholera. She is exposed daily, however, to dangers from her infected neighbors. On the Polish frontier danger threatens constantly. On the Austrian border the danger is fully as great, while all efforts to guard against it are likely to be rendered futile by the lying of the Hungarian authorities. The Hungarian Minister of the Interior is doing his best to obtain truthful reports from the infected districts, but he is thwarted by the local authorities. Some of the city and district officials suppress cholera news simply because they are too shiftless and ignorant to see the need of obeying the orders of the Home Office. Others do not report cases because they fear to annoy the people whose votes will be valuable at the next election. The people in most of the infected districts are reckless and illiterate. Most of them are dirty and dislike to be roused, cleansed and fumigated. The cholera spreads, therefore, almost unchecked among them, and nobody hears of it until the increasing mortality causes a panic.

Dr. Dunbar, Director of the Hygienic Institute in Hamburg, has tested seventy-seven samples of water from the Elbe and its affluents since July 19th. He has found bacteria in twenty samples, but in no case the genuine bacilli of Asiatic cholera.

There were eight deaths from cholera in Naples, on August 26th. It is reported that nineteen cases of cholera and five deaths have occurred at Palermo. On August 29th Naples was declared free from cholera. One case of cholera and two deaths were reported at Salerno, and three deaths at Cassino.

During the week ending August 26th, the following reports were received from the Russian provinces: Orel, 820 cases and 325 deaths; Tula, 653 new cases and 139 deaths; Kieff, 678 new cases and 227 deaths; Kazan, 230 cases and 88 deaths; Jaroslav, 193 new cases and 79 deaths; Don, 163 new cases and 113 deaths; Samara, 177 new cases and 68 deaths; Veronesh, 172 new cases and 88 deaths; Mohileff, 135 new cases and 48 deaths; Poltava, 134 new cases and 64 deaths; Kuban, 110 new cases and 93 deaths; Taurida, 115 new cases and 43 deaths; Grodno, 114 new cases and 34 deaths; Moscow, 110 new cases and 40 deaths; Ekaterinoslav, 79 new cases and 38 deaths; Minsk, 97 new cases and 49 deaths; Kharkoff, 99 new cases and 63 deaths; Kherson, 83 new cases and 20 deaths; Tchernigoff, 49 new cases and 19 deaths; Viatka, 64 new cases and 30 deaths; Simbirsk, 50 new cases and 23 deaths.

There are known to have been nine cholera suspects in St. Petersburg during the preceding week. In Kertch, in the Crimea, there were 44 new cases and 24 deaths. In Sebastopol the new cases numbered 9 and the deaths 6 in the last week.

From Paris it is cabled that a suspicious malady, supposed to be cholera, has broken out at Nantes, from which many persons are suffering.

Anton Weichselbaum has been unanimously elected as the successor of Kundrat, recently deceased, in the chair of pathologic anatomy, at Vienna. There seems no doubt that the election will be confirmed by the Minister of Education. Weichselbaum, who is forty-nine years old and since 1885 has been Professor Extraordinary of Pathologic Anatomy, has already gained distinction as a pathologist and bacteriologist.

Dr. Edmund Neisser has been appointed Professor of Special Medical Pathology and Therapeutics and Director of the Second Medical Clinic, at Vienna, to fill the vacancy created by the death of Otto Kahler.

Professor Hayem has resigned the Chair of Therapeutics at Paris to accept that of Clinical Medicine, recently rendered vacant by the death of Professor Peter.

SOME FACTS BEARING ON THE CONDITION AND SERVICEABLENESS OF THE STUMP AFTER AMPUTATIONS IN THE LOWER EXTREMITY AT DIFFERENT POINTS AND BY VARIOUS METHODS.[1]

BY STEPHEN SMITH, M.D.,
OF NEW YORK.

DURING the latter years of the civil war of the United States I was one of the surgeons to a military hospital located in the city of New York, to which were sent large numbers of soldiers requiring artificial limbs. These cases were individually studied with great care, and full records were made of all of the useful facts connected with them. Many of the deductions then made from these facts do not now have the force which they then had, owing to the influence of antiseptic methods on the results of the treatment of amputation-wounds. There were some features, however, of the investigation then made of a more permanent value, and which may prove instructive to the members of this section. It is in that view that they are brought forward in this paper.

1. INFLUENCE OF THE PLACE OF AMPUTATION UPON THE AMOUNT OF ATROPHY OF THE STUMP.

Among the final results of amputations, atrophy of the stump must be regarded as of the first consideration. Next in value to a firm and durable covering to the stump is a well-nourished extremity. If the stump undergo progressive atrophy, the artificial limb requires much more care to maintain its adaptation. The constant shrinkage of the extremity renders the appliance loose, and hence it requires readjustment by continuous padding of the socket. This padding of the socket is not required when the limb maintains its full dimensions.

The accompanying tables enable us to determine how far the method of operating and the point of the limb at which the amputation is performed influence the subsequent nourishment of the stump. The measurements were made when the stump was healed and prepared for the final adjustment of the artificial limb. The first or proximal measurement was made in the thigh at the highest point where the circumference could be taken, and in the leg immediately below the knee. The second, or distal measurement, was made directly around the extremity of the stump, at a point where the margins of the flap begin to incline toward the cicatrix. The figures entered in the tables under the head "atrophy," express the difference in inches and fractions of an inch between the measurement at the points indicated on the mutilated and uninjured limb.

COMPARATIVE AMOUNT OF ATROPHY OF STUMPS IN THE UPPER MIDDLE AND LOWER THIRDS OF THE THIGH AND LEG, IN THE AGGREGATE OF 430 CASES.
(In inches and fractions of inches.)

Limb.	Upper Third.		Middle Third.		Lower Third.	
	Proximal	Distal.	Proximal.	Distal.	Proximal.	Distal.
Thigh	0.45	1.05	1.56	1.70	1.34	2.08
Leg	0.97	1.70	0 71	1.42	0.57	2.26

It must be borne in mind that the proximal measurements in the thigh are all made at the same point; and the same is true of the leg. It would appear from this table that the point of amputation exercises a very marked influence upon the degree of atrophy of the stump, both in the thigh and leg. In general, the amount of atrophy progressively increases as we recede from the trunk, an exception, however, being noticed in the middle third of both the leg and thigh, which we shall presently notice. In the thigh the proximal atrophy is least in amputations in the upper third, and greatest in amputations in the middle third. In amputations in the lower third of the thigh the proximal atrophy is slightly less than in those performed in the middle third, but still it is three times as great as after those in the upper third. This fact proves a progressive proximal atrophy as the point of amputation in the thigh recedes from the trunk. In the leg this rule is reversed, and the proximal atrophy diminishes as the point of amputation recedes. And this atrophy diminishes in regular order, being least in amputations in the lower third of the leg.

It must not be supposed that the proximal atrophy is influenced by the amount of inflammatory thickening subsequent to the operation, for in that case the degree of atrophy would in general depend upon the proximity of the amputation to the point of measurement. But this is by no means the case. Amputations in the middle third of the thigh, near

[1] Read before the Section on Military Surgery of the Pan-American Medical Congress, September 7, 1893.

the point of measurement, are followed by a greater amount of atrophy than those in the lower third, remote from that point; while in the leg the largest amount of atrophy is in amputations near, and the least in amputations remote from, the point of measurement.

The distal atrophy, or that which occurs at the extremity of the stump, has in the thigh a progressive increase as we proceed from the trunk, being about twice as great in the lower as in the upper third. In the leg, on the contrary, the least distal atrophy occurs in the middle third, while that of the lower extremity is not so great, compared with that of the upper extremity, as was found existing between the upper and lower thirds of the thigh.

Comparing the atrophy of the stumps in thigh and leg amputations, we notice that the proximal atrophy is greater in amputations in the upper third of the leg than in the same region of the thigh, while in the middle third it is more than twice as great in the thigh as in the leg, and in the lower third the excess of atrophy is proportionately greater in the thigh than in the leg. The distal atrophy varies very markedly as follows, namely: In the upper third it is greater in the leg; in the middle third it is greater in the thigh; and in the lower third it is again greater in the leg.

These facts may be stated in general terms as follows:

1. In the thigh, the farther amputation is performed from the trunk the greater will be the atrophy of the entire stump.

2. In the leg, the farther amputation is performed from the trunk the greater will be the atrophy of the extremity of the stump and the less the atrophy of the body of the stump.

2. INFLUENCE OF THE METHOD OF AMPUTATION UPON THE ATROPHY OF THE STUMP.

We next proceed to inquire as to the influence of different methods of amputation upon the nourishment of the stump.

The accompanying table contains a distribution of the several methods of amputation in the thigh and leg, with a computation of the average amount of atrophy following each.

This table illustrates in a very striking manner the influence of the various methods of forming the covering of the stump upon the nourishment of its cicatricial tissue. The difference in the amount of atrophy of the distal extremity evidently depends upon the extent to which the arterial supply has been sacrificed. In the thigh the arteries which are distributed to the muscles arise principally, in the upper third, from the femoral branches immediately below Poupart's ligament, and in the middle and lower thirds from the profunda.

COMPARATIVE AMOUNT OF ATROPHY OF STUMPS AFTER AMPUTATION BY VARIOUS METHODS IN THE UPPER, MIDDLE, AND LOWER THIRDS OF THE THIGH AND LEG.

(In inches and fractions of an inch.)

Method.	Upper Third		Middle Third		Lower Third	
	Proximal.	Distal.	Proximal.	Distal.	Proximal.	Distal.
Thigh. (Total number of stumps, 157.)						
Circular	0.7	0.7	1.4	1.9	1.6	2.5
Antero-posterior flaps	0.2	1.4	1.1	1.6	1.6	2.4
Lateral flaps	...	...	1.8	1.8	1.6	2.3
Anterior flap	...	...	2.5	2.2	1.3	2.4
Rectangular flap	...	...	1.0	0.0	2.0	2.8
Skin-flaps and cir. muscles	...	...	...	...	0 6	1.5
Posterior flap	...	...	...	...	0.7	0.7
Leg. (Total number of stumps, 287)						
Circular	1.1	1.5	1.0	2.3	0.5	2.3
Antero-posterior flaps	1.1	1 3	0.4	1.1	0.1	2.7
Posterior flap	1.3	1.1	0.5	2.2	1.0	2.6
Lateral flaps	0.4	2.9	1.0	1 0	0.7	2.6
Skin-flaps and cir. muscles	...	...	...	...	0.5	1.1

In the upper third of the thigh, therefore, a circular amputation would divide the branches of the femoral at a higher point than an antero-posterior flap—in which the posterior flap is usually longer than the anterior—and hence the atrophy would be greater in a stump formed by a circular than in one formed by an antero-posterior flap. The same rule would apply to these operations in other parts of the thigh, though perhaps not so markedly.

The method of operation by lateral flaps does not differ materially, in respect to the degree of atrophy, from the circular, and the results of the two are seen to be very similar.

The method of operation by making an anterior and rectangular flap differs in this important respect from the preceding methods, namely, that the flap is made wholly from the anterior part of the limb, while the tissues are completely divided to the bone in a perpendicular direction on the posterior aspect of the limb. By these methods the principal covering of the stump is poorly supplied with nourishment, and hence atrophy would be more likely to occur. This is seen to be the case especially in the anterior-flap method in the middle third and the rectangular flap in the lower third.

The methods which give the least atrophy of the stump, both in its proximal and distal portions, are the skin-flaps and circular of the muscles and the posterior flap. It is not difficult to understand why the posterior-flap method gives results so favorable; it leaves quite intact the full vascular supply to the entire covering of the stump. In this respect it might well be regarded as the best method of operation in the thigh; but these advantages are so

counterbalanced by the tendency of the flap to retain pus, its heavy and unsuitable position for transportation, etc., that it has but few advocates. The method by skin-flaps and circular of the muscles gives results nearly as favorable as the posterior flap, and much more favorable than any other of the preceding methods. It is greatly preferable to the posterior-flap method, both on account of the facility of drainage and the neat apposition and lightness of the flaps, thus adapting it to transportation.

The influence of the various methods of operation upon the nourishment of the stump is not so well marked in the leg as in the thigh. This is unquestionably due to the peculiarity of the arterial distribution. The larger trunks are numerous and are deeply situated in immediate relations with the bones. They are not, therefore, liable to division until the operation is about to be completed. There would, therefore, be but little difference among these operations as regards the vascular supply of the flaps, except so far as the extent of the flap should modify the ultimate distribution of arteries. A long flap would necessarily have less supply than a short flap, and would be more liable to immediate death and future atrophy. Of the different methods it will be noticed that the skin-flaps and circular of the muscles give the least atrophy in the leg, as well as in the thigh.

3. COMPARATIVE VALUE OF STUMPS IN AMPUTATIONS IN THE LOWER THIRD OF THE LEG AND AT THE ANKLE-JOINT.

It must be observed that amputation at the ankle-joint is always an alternative operation. It is selected in preference to an amputation at a point higher up on the limb. It should also be added that it is an operation of expediency. It is not a *dernier ressort.* If it fails of success the surgeon may still, with rare exceptions, perform the alternative amputation through the leg, with the prospect of as favorable results as when the latter is the first operation.

In determining the value of ankle-joint amputations, therefore, the following questions naturally arise for our consideration:

The comparative serviceableness of the resulting stump depends upon—

(*a*) The ability for unaided locomotion on the stump.

(*b*) The adaptation of the stump for an artificial limb.

(*a*) *As regards unaided locomotion on the stump.*—Ankle-joint amputations differ from amputations in the leg in this essential particular, namely: in the former the support is taken directly upon the extremity of the stump, and in the latter upon the sides of the limb. In model stumps of each class it will be found that the one which takes direct support upon the extremity is not only capable of enduring a much larger degree of service, but the person suffers far less inconvenience. Direct pressure upon the heel-flap may be endured as long in Syme's stump as similar pressure upon the natural heel. And the same is true of stumps following Pirogoff's method. Patients with these stumps have frequently been known to walk successive days twenty and thirty miles with only the simple covering or protection of the heel of a common shoe or boot. These are by no means exceptional cases. Surgeons who have been accustomed to meet with the results of this operation most frequently uniformly testify to the ease with which patients betake themselves to the stump with only such covering as they can rudely adjust. Of the stumps left by Syme's and Pirogoff's operation, the latter has the geater length, and this requires less compensation.

Amputations through the leg, at whatever point and however skilfully performed, never furnish stumps which take direct support.[1] The limb is useless for locomotion by any simple means of compensation; it is only when an artificial limb is accurately and skilfully adjusted that it serves the purpose of even simple progression.

Again, in amputation at the ankle-joint the patient retains power over the muscles of the calf, which are essential to the act of running. It is extremely rare that a patient who has suffered amputation of the leg can make even the pretence of running upon his artificial limb. The muscles, especially of the calf, have shrunk from disuse, and progressive, permanent atrophy of the parts below the knee ensues. In ankle-joint amputations, however, the tendons of all the muscles employed in locomotion retain their former or acquire new attachments, and are immediately and constantly exercised in the movements of the limb. It is true that this movement of the muscles is more limited than in the normal limb, but it is, nevertheless, sufficiently great to preserve much of their activity, and consequently their nutrition is but partially impaired. The importance of preserving the functions of the muscles of the leg is seen in the perfection of gait which persons with ankle-joint amputations soon acquire. They can not only run, often with great ease and facility, but they also acquire the power of leaping, dancing, etc., to such perfection that their disability frequently passes unrecognized.

[1] Truax, an experienced manufacturer of artificial limbs, makes this statement: "When a section has been made through a bone no weight can be borne on the end of the stump. Disarticulation or an osteoplastic operation alone will admit of pressure."—"Amputations in the Light of Prothetical Science."

(*b*) *As regards the adaptation of the stump for an artificial limb.*—As previously stated, the stump after ankle-joint amputation takes direct support upon the extremity. Mr. Quain thus speaks of the advantages of direct support in referring to Syme's amputation: "It is free from any valid objection, and, what is more important, the result in practice has been found to be good. A person who has undergone this operation is enabled to bear his whole weight upon the end of the stump without inconvenience; and on this account the facility of progression is, with a proper apparatus, decidedly greater than when the amputation is performed at any higher part of the limb."

The advantages of the ankle-joint stump over those of the leg for the adaptation of an artificial limb are admitted by the most competent mechanical surgeons to be of the most undoubted character. In Syme's amputation the patient walks upon the end of the stump with ease and grace, can run, leap, and dance, and is capable of enduring fatigue little short of that of the sound limb. Dr. E. D. Hudson, of New York, a most skilful mechanical surgeon, and who was selected by the government to apply artificial limbs to the soldiers in the hospital referred to, states that in fifty cases of ankle-joint stumps to which he applied limbs he had not met with a single instance in which the stump did not, after preparatory treatment, take direct pressure without inconvenience and give a most happy result. No results at all comparable with these are attainable with any form of stump above the ankle.

This review of the comparative merits of ankle-joint and leg amputations, as exhibited by statistical evidence, authorizes the following conclusions:

1. The stumps left after ankle-joint amputations are far more serviceable for unassisted locomotion than those resulting from leg-amputation.

2. An artificial limb can be far more usefully applied to an ankle-joint than to a leg stump.

SHOULD INEBRIATES BE PUNISHED BY DEATH FOR CRIME COMMITTED WHILE INTOXICATED?[1]

BY T. D. CROTHERS, M.D.,
SUPERINTENDENT OF WALNUT LODGE HOSPITAL, ETC., HARTFORD, CONN.

A NEGATIVE answer to this question is an evolutionary growth, coming into prominence uninfluenced by legal rulings or personal opinions.

It is asserted that over five hundred homicides occur every year in this country in which this question comes up.

In every case it is met by the statement of the law "that drunkenness in law is no excuse for crime," and this is urged as if it were a fixed principle. Three hundred years ago Lord Coke, of England, decided that inebriety always aggravated the offence, and the punishment should be rather increased from this fact. This view has been the theory for the legal treatment of inebriety up to the present. It practically assumes that inebriety is a phase of savagery, and a tendency to lawlessness, or giving up all control or restraint of the lower animal impulses without regard to law, order, or society. An ethical and moral theory of inebriety calls this moral depravity and an innate vicious impulse. The remedy urged from these theories is severe punishment and suffering—the vengeance of the law, intimidation, pain, loss, and so on.

The *modern scientific view* affirms inebriety to be a physical condition of degeneration and disease, inherited or acquired, and at all times a modified form of insanity. The use of alcohol is in many cases only a symptom of degeneration, and in all cases it not only produces changes of brain-circulation, congestion, paralysis, and impairment of all functions and organic processes, but it kindles into activity latent degenerations and tendencies, the result of which is incapacity to reason, with imperfect control and damaged senses. The inebriate cannot be a normal, sane man.

The practical question to be determined is the possibility of anyone using spirits to excess, at intervals or continuously, without impairing his judgment and power of control.

Intoxication, whether associated with delirium or stupor, is always a condition of brain-paralysis and poisoning in which the mind is incapable of acting normally. This condition is recognized as insanity, and has all the symptoms, only varying in duration, and is followed by a return to former health. The more frequent the intoxication, the greater the injury to the brain; and the shorter the intervals between these attacks of poisoning, the more doubtful restoration would be to follow. These facts are self-evident, and crime committed when in the intoxicated state would always be the act of a madman.

In a casual grouping of twenty murders reported in the daily papers, in every instance the account described the criminal as intoxicated or drinking heavily at the time of the commission of the crime. In four cases the criminal had awakened from the stupor of intoxication, and drank again before the acts committed.

In all such cases the obviously unsound brains, and mental incapacity to either reason or control, must be beyond question. At this point the law urges the most presumptuous fiction, viz., that this state of madness is voluntary and within the control of the victim, who should be punished for using

[1] Read before the Section on Medical Jurisprudence of the Pan American Medical Congress, held in Washington, D. C., September 5, 6, 7, and 8, 1893.

spirit with full knowledge of its effects on his mind and conduct. This assumption, if true, must necessarily be founded on physiologic and psychologic facts that are far beyond all present knowledge. A brief outline of some of the effects of alcohol on the brain will make this clearer.

To-day it is shown that the action of alcohol on the brain and nervous system is anesthetic and paralyzant. The use of alcohol to excess at intervals or continuously always numbs and paralyzes the higher operations of the brain; the over-stimulated heart reacts and depression and feebleness follow. All the senses are disturbed and become more or less incapable of transmitting the impressions which are received. The brain cannot accurately comprehend the nature of acts and the relation of surroundings when under the influence of alcohol. The palsy which follows from this drug masks brain-function. Delusions of vigor and strength appear; events, their consequences, and motive and conduct, are all exaggerated, misconceived, and misinterpreted, and the brain is unable to correct them. The pronounced delusions, illusions, delirium, mania, imbecility, and stupor seen in states of intoxication are only the advanced stages of brain-conditions which begin with the first glass of spirit. The early-changed conduct and speech of men who use spirit are the first symptoms of the paralyzing action of alcohol. More spirit is followed by more paralysis, and finally all judgment and experience and all distinctions of right and wrong, of duty and obligation, are confused and unreal. The supposed brilliancy which follows the use of spirit is unreal and transient—it is the glamor of the mind which has lost its balance and is unable to correct itself. No other drugs are known, the paralyzing effects of which on the higher brain-centers are so positive and insidious. The inebriate and moderate drinker have always impaired brain-force and nerve-power. The automatic nature of their life and brain-work may cover up this fact; but change the surroundings and demands on the brain, and its incapacity appears. Every toxic state from alcohol more or less permanently impresses and debilitates brain-integrity.

The fear of the law and the consequences of acts make little impression in such cases. The brain is anesthetized and crippled, and cannot realize events and their nature and consequences. The more pronounced the inebriety and the longer its duration, the more positive the disease and incompetency to reason and control acts. The effort to fix a point in all disputed cases where sanity and responsibility join insanity and irresponsibility is an impossibility which every advance of science demonstrates. It is equally impossible to use alcohol to excess for years and have a sound, normal brain. It is impossible in such a case to fully realize the nature and consequence of acts and obligations. It is a legal fiction to suppose that a crime committed while under the influence of alcohol is the voluntary act of a sane man. It is a legal fiction to suppose that a sane man would plan a crime, then become intoxicated for the purpose of executing it. It is a legal fiction to suppose that premeditation in crime committed by an inebriate is evidence of sanity and consciousness of his acts. These are some of the facts of science which bring additional evidence of the error of capital punishment in such cases.

A study of the crimes committed by inebriates amply confirms the facts of brain-incapacity and brain-disease. Thus in cases of capital crime by inebriates, delusions, illusions, morbid impulses, and epileptic explosions are common symptoms. In many cases capital crime is the result of peculiar circumstances and sudden strains on the enfeebled brain, or the possession of a morbid impulse, a delusion or illusion that suddenly dominates the mind; also epileptic explosions, that are real attacks of maniacal fury and unreason. Alcoholic somnambulism or trance is present in many cases. The mind in these cases is oblivious to all outside influences or considerations and is subject to every passing impulse that may come from either external or internal causes. At the time no general indications of unconsciousness may be present, yet a certain automatic line of conduct and history of crime give clear hints of brain-enfeeblement. All crime by inebriates will be found associated with concealed or open delusions, morbid and epileptic impulses, and sense-deceptions. In all of these cases the brain is unsound and cannot act rationally and clearly. There are present in these cases either the insanity of inebriety or the inebriety of insanity. The inebriety of the prisoner has merged into insanity, and this concealed insanity or brain-degeneration has developed into inebriety or dipsomania. The death-penalty has no horrors for such cases. It is rather welcomed. The struggle for life is the attractive publicity that makes the hero of the man, and the mystery of the end of life intensifies the interest to the last moment. A form of delirious exaltation manifest in religious faith or a martyr's innocence sheds a mysterious glamor over the execution of the law that has no terrors.

In England, a century ago, when public executions for thieving were common, thieves and pick-pockets committed the same crimes in the crowds about the gallows. To-day the execution of an inebriate murderer, when all the details of the crime are made public, becomes an object-lesson, closely followed by inebriates who commit exactly similar crimes, in a similar manner.

The natural history of such cases is continuous punishment for inebriety, assault, theft, burglary, and petty crime, and finally murder. Each period of punishment is followed by the same or a more aggravated crime. The intent and purpose of the law is defeated, and this means of treatment both directly and indirectly increases crime and prepares the inebriate for worse and more hopeless states. The courts and prison officials are powerless; public opinion sustains the law and demands its execution irrespective of all consequences. The poor victims punished to-day reappear to-morrow, under arrest for the same or a worse crime. The severity of the punishment makes no difference. The inebriate who, under the influence of alcohol, commits assault to-day will do so to-morrow, and next year, and so on, as long as his inebriety continues. No legal punishment of fines and imprisonment can stop him. These facts are sustained by the experience of all courts and prison officials. They also apply equally to the death-punishment of inebriates for crime.

When the crime is the direct or indirect result of inebriety, it is only the natural outcome or logical result of conditions of brain-disorder and surroundings. The assumption that inebriety is always a voluntary condition within the control of the person, is a most fatal error. On this error is based the death-penalty. Its practical failure is apparent in the increase of capital crime by inebriates. The inebriate who has been arrested for petty crime while intoxicated many times before, finally commits murder in the same condition, and is executed. His friends and companions do the same thing and suffer the same penalty. Thus one brutal murder committed in a state of intoxication is followed by another equally brutal, and the execution of the murderer makes no diminution in the number of similar crimes that follow.

In every daily paper appear records of the same murders by inebriates under the same circumstances. A wave of public vengeance may dispose of the criminal by lynch-law, or only be satisfied when he is hung, but the same murders are committed again by the same class of men. This is only the repetition of the same blunder of fining and imprisoning inebriates for inebriety and petty crime. In both cases the victims are destroyed and similar offences are increased rather than diminished. In one case imprisonment and fines make the inebriate more incurable and less capable of change of life and living; in the other, the execution of the inebriate leaves a brutalizing, combative influence and a form of contagious glamor that defective brains are powerless to resist. These are the facts which experience and observation fully confirm, and which the latest teachings of science explain and point out.

A summary of the facts that we have outlined would sustain the following statements:

1. The legal treatment of insanity has changed in obedience to a more accurate knowledge of the brain and its diseases.

2. The legal treatment of inebriety is unchanged to-day. Although it occupies two-thirds of the time of courts, all teachings of science and a larger knowledge of the inebriate and his malady are ignored.

3. The ruinous error of punishment by fines and imprisonment of inebriety, and petty crimes associated with it, which notoriously increases and perpetuates the inebriate and criminal, is a fact demonstrable in every community.

4. Thus public opinion, through medieval theories and laws, is training and preparing a class of inebriates who first commit petty, then capital crime, with a certainty that can almost be predicted.

5. The death-penalty for such crime utterly fails for the same reason. The execution of any number of this class simply opens the door for an army already prepared and trained to take their places.

6. From a scientific study of these cases, it is clearly apparent that they are diseased and incapacitated to act sanely. Alcohol has palsied the brain and made them madmen. The very fact of the continuous use of alcohol is evidence of mental impairment and unreasoning act and thought.

7. To hold such men accountable for their acts, and by punishment expect to deter them from further crime, and by such punishment check others from similar crime, is an error which both scientific teaching and experience point out.

8. The object of the State, through the law, is to protect society and the individual; but if the execution of the law-breaker fails to accomplish this end, the laws are wrong.

9. The unfounded fear that the plea of insanity in crime, and the failure to punish, constitute an encouragement for further crime, is flatly contradicted by statistics.

10. Among the mentally defective, the insane, and inebriates, the death-penalty is followed by an increase rather than a diminution of crime.

11. The inebriate should never be hung for crime committed while under the influence of alcohol.

12. This method of punishment is never deterrent, but furnishes an attraction for other inebriates who commit similar crimes in the same way, following some law of mental contagion.

13. The inebriate murderer should be confined for the rest of his life in a military work-house hospital. He should be under the care of others, as incapacitated to enjoy liberty and incompetent to direct his thoughts or acts.

14. A change of public sentiment and law is

demanded, and a readjustment of theory and practice called for. The criminal inebriate occupies a very large space among the armies of the defective who threaten society to-day, and his care and treatment must be based on accurate knowledge, and not on theory.

15. Inebriate murderers should never be placed on public trial, where the details of the crime are made prominent or the farcical questions of sanity are publicly tested. They should be made the subject of private inquiry, and placed quietly in a work-house hospital, buried away from all knowledge or observation of the world.

16. The contagion of the crime and punishment would be avoided, and the inebriate's services might repair some of the losses to society and the world.

MALLET-FINGER.[1]

BY ROBERT T. MORRIS, M.D.,
OF NEW YORK.

THE deformity here described is not uncommon among men who engage in athletic sports.

When the extensor tendons of the fingers are tense, a blow upon the end of a finger transmitting force in a direction which would ordinarily flex the finger, results in injury to the extensor tendon in the vicinity of its attachment to the dorsal surface of the last phalanx. The injury consists, not in a bodily separation of the tendon from its points of attachment, but rather in a thinning of the tendon cephalad from the principal point of attachment to the phalanx, and from the fibers that form the

FIG. 1.

Mallet-finger. (Showing permanent dropping of tip of forefinger.)

posterior ligament of the last phalangeal articulation. A few fibers of the tendons are undoubtedly ruptured, but most of them slide away from each other very much as the threads of a textile fabric separate when the fabric is violently stretched, but not torn, the structure retaining its original general appearance.

[1] Read before the Section on Anatomy of the Pan-American Medical Congress, Washington, September, 1893.

Immediately after the occurrence of the injury to the tendon the last phalanx of the finger assumes a semi-flexed position, and the deformity is usually permanent, the extensor tendon then having little

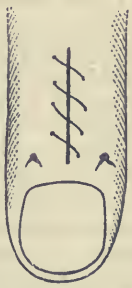
FIG. 2.

Extensor tendon of index finger thinned by artificial production of mallet-finger upon the cadaver.

or no influence upon the freed phalanx. Aside from the uncanny appearance of such a finger, the deformity is a source of much annoyance to the patient.

The tendon is repaired without much difficulty by making a longitudinal incision two centimeters in length over the site of the injury, dividing the

FIG. 3.



End of finger, showing line of incision and sutures. The two black dots mark the points at which the fasciculi and tendon are sutured to the skin.

thinned tendon longitudinally into the two principal fasciculi into which it naturally separates, dividing the tendon transversely, cephalad from the thinnest point, and advancing each fasciculus to a point upon its own side of the finger, near the base of the finger-nail. At this point the fasciculus is sutured to the under surface of the skin with a suture which passes through the skin, and is tied upon the outside. The fasciculi are sutured to skin rather than to periosteum and tendinous remains, because the former structure affords a firmer hold and the cut end of the tendon makes as good union with the phalanx as it would if sutured directly to periosteum.

The finger-nail is sometimes lost temporarily as a result of the operative disturbance near its matrix.

FIG 4.

Temporary flexion at middle phalangeal articulation after advancement of extensor tendon.

When the advanced fasciculi are sutured in place there is an over-correction of the deformity of the phalanx, which causes also a flexion at the middle phalangeal articulation. This condition is temporary and disappears spontaneously in a few weeks, leaving a perfect finger.

CLINICAL MEMORANDA.

THE REMOVAL OF STONE IN THE BLADDER; LITHOLAPAXY.

BY W. S. FORBES, M.D.,
OF PHILADELPHIA;
PROFESSOR OF GENERAL, DESCRIPTIVE, AND SURGICAL ANATOMY IN JEFFERSON MEDICAL COLLEGE, AND CLINICAL SURGEON TO JEFFERSON MEDICAL COLLEGE HOSPITAL.

IN reporting the following five cases in my list of patients with stone in the bladder, and on each of whom I performed the operation of crushing the stone and removing the fragments and débris from the bladder at one sitting (litholapaxy), I desire to call attention to the range of years in the patients, and to emphasize the fact of the successful application of litholapaxy to the young child as well as to the old man.

The oldest patient was eighty, and the youngest was three years of age.

The old man had a very large prostate gland, but was otherwise in good condition. In the child, of course, the gland was but rudimentary, yet in each case the appropriate lithotrite and canula were used with ease, and there was the happiest result in crushing and removing the fragments.

CASE I.—J. W., of Virginia, aged eighty years, was examined on February 1, 1893, and on February 8th the stone, of the uric acid variety, was crushed and removed. On the 15th of February he went home well. The weight of the fragments was 136 grains.

CASE II.—G. W. C., of Erie, Pa., aged fifty-five years; brought to me by Mr. O. C. Aichner, a member of my class; was examined on the 25th of January, 1893. On the 29th the stone was crushed and removed. On the 6th of February he returned home, well. The fragments weighed 90 grains. It was of the oxalate of lime class.

CASE III.—C. A., of Philadelphia, twenty-three years of age; also brought to me by Mr. Aichner; was examined on February 15, 1893. On the 20th inst. the stone was crushed and removed. He was discharged on February 28th, well. The fragments weighed 80 grains. The stone was phosfate of lime.

CASE IV.—J. B. M., of Mercersburg, Pa., seventeen years of age; brought tome by my friend Dr. E. A. Hudson, of Mercersburg. He was examined on February 7, 1893. This young man had suffered from symptoms of stone for ten years. He was a farmer's boy. His bladder was capable of holding only two ounces of water, and its walls were much thickened. On the 18th of February the stone was crushed and removed. He went home well on March 1st. The fragments weighed 320 grains, and their composition was uric acid and phosphates. The stone had a large and very hard and tough uric acid nucleus.

CASE V.—B. O. D., of Philadelphia, was three years of age. This child had symptoms of stone for more than a year. He was examined on the 28th of January, 1893. The stone was crushed with a No. 10 (American scale) lithotrite, and the fragments removed on February 3d. He went home well on March 1st. The fragments weighed 70 grains. The composition was uric acid.

In every one of these cases the bladder was washed out previously to the operation with a mild sterilizing lotion—bichlorid of mercury and warm water, 1 : 10,000. At the moment of operation all urine was drawn off, and, according to the size of the bladder, from two to six ounces of the boric solution injected. After the operation the bladder was well washed with a warm boric solution, and after this a large hot hop-poultice was applied to the entire abdomen.

Ether was used on every occasion.

1704 WALNUT STREET.

DISEASE OF THE MIDDLE EAR INVOLVING THE MASTOID PROCESS.

BY W. F. CONNERS, M.D.,
OF OIL CITY, PA.

ON February 23d, Dr. Jas. B. Siggins, of Tionesta, kindly asked me to see a case of ear-disease with him. The patient, Mrs. A. M. D., twenty-eight years old, delicate and reduced by an attack of influenza, was seized with sore-throat about two weeks previously, with pain in the right ear, which shortly afterward began to discharge a large amount of pus. All went well for a few days, when the left ear began to discharge. A few days before I saw the patient, the right ear had ceased to run and the mastoid process of that side had become very painful. On the day before I saw her the woman had several "sinking" spells, with semi-coma, at times being delirious and roused with difficulty. The pain had been combated with hot external applications, which could no longer be borne. On examination, the bony part of the auditory canal was found to be filled with a whitish detritus, and nearly closed. After a hot carbolized douche the ear-drum was found floating in the basin, having been washed out of the ear. The hearing

in the right ear was *nil* and one had to speak loudly into the left in order to be understood. The left drum was gone, except for a narrow rim in the center around the handle of the malleus, which looked red and was bathed in pus. No tenderness of the left mastoid was observed. Owing to the weak condition of the patient we deferred operating on the mastoid and decided upon adding quinin and iron to the strychnin which the patient was taking, and morphin to control the pain. During the next few days, the douche being continued, the patient made some improvement, but got little relief from the mastoid symptoms. Four leeches were tried, but they caused so much pain that they could not be kept on. I saw the patient again on the 28th, and finding the right canal much congested, opened it freely along its lower part. There followed a free flow of blood, which for a time relieved the pain. I did not see the left ear for want of time, but learned that it still ran moderately. The tenderness over the right mastoid was less, and a poultice could now be borne. I directed a cantharidal plaster an inch square to be applied to the mastoid just behind and slightly below the auditory meatus. The night of the 28th and the day of the 29th were both bad ones. They were followed by an erysipelatous eruption over the right half of the head, preceded by marked congestion of both eyes, and with entire relief from the pain over the right mastoid and ear. On the morning of March 2d patient complained of a bad taste in the mouth and for several weeks expectorated large quantities of fetid pus, at times mixed with blood. The quinin was replaced by tincture of ferric chlorid.

Three months later I examined both ears at my office; found the drums healthy and the hearing-distance, for a watch, about three feet, with scarcely any evidence of the imperilling condition in which the woman had been.

SOME OBSERVATIONS ON A CASE OF COMPOUND FRACTURE OF THE SKULL.

BY J. CHALMERS DA COSTA, M.D.,
OF PHILADELPHIA;
DEMONSTRATOR OF SURGERY IN JEFFERSON MEDICAL COLLEGE.

A RECITAL of the following case will illustrate some facts from which conclusions of great practical importance can be deduced.

Mr. G., forty years old, a commercial traveller, was struck on the head with a cane during a street-brawl. He was temporarily unconscious, but, on reaching the hospital, was found to be perfectly conscious. An examination made ten hours after the accident showed the man to be spare and of medium height, apparently healthy and well nourished. There was a contused wound over the left eyebrow, leading down to uninjured bone, and inflicted by falling down upon the face when struck. Both eyes were blackened; the conjunctiva much injected; the face discolored; the pupils equal and normal in size and reaction. There was a contused wound, one inch long, upon the right side, over the posterior inferior portion of the parietal bone, which bone, touch disclosed, was very decidedly depressed. The mind of the patient was entirely clear; he was able to detail with calmness and accuracy the events leading up to the assault. Moderate pain was felt about the fracture, in addition to a general dull headache, but there was no spasm, no paralysis, no affection of bladder or rectum.

In spite of the entire absence of cerebral symptoms, the extent of the depression and the fact that the fracture was compound led me to advise trephining, which recommendation was approved of by Professor Keen. The scalp having been previously shaved and rendered surgically clean, the patient was at once etherized and the parts exposed by a free incision. The bone was trephined and a button removed from the end of the split toward the vertex. The inner table exhibited extensive splintering, large fragments having been driven deeply under the edge of firm bone, thus widely separating the dura. At least an ounce of fresh blood escaped on removing the button and lifting the depressed fragments; the blood was seen to have come from a laceration of a posterior branch of the middle meningeal artery, which was still bleeding. There was also a great amount of blood welling up from under the lower edge of the wound, some radicle of the lateral sinus having suffered. All of the fragments were removed; the bony edges were cut smooth with the rongeur; the bleeding from the artery was arrested by passing catgut ligatures around the vessel on each side of the rent; the bleeding from the vein was checked by packing with iodoform-gauze. The fragments were not replaced. The end of the gauze projected out of the wound, the edges of which were approximated with sutures of silkworm-gut. The wound of the forehead was also sewed up. It seems needless to state that we were most careful to cleanse the wound and to keep it clean. Dressings of corrosive gauze were applied and the patient returned to bed.

The morning after the operation the temperature was 101°, but it fell to normal under the influence of a purgative, and the following morning, forty-eight hours after the accident, the packing was removed. Now came a question. None of us could remember absolutely how many pieces were used. I should have known, but did not, and, instead, believed that there were two, but only one could be found by a careful search. We determined to await developments. The case progressed most favorably. The wound healed by first intention, except at a small point where the packing had projected and at which point a few drops of serum escaped daily. On the seventh day the stitches were removed, and our apprehensions were entirely allayed as to any foreign body being retained within the skull.

For ten days there was not a bad symptom, but on the eleventh day the patient was most peculiarly garrulous, irritable, and complaining. An eye-examination made by Prof. de Schweinitz showed evidence of increased pressure. The man passed a bad night, and on the twelfth day was restless, excessively talkative, complaining loudly and angrily, and asserting that people were in league to injure him. On the thirteenth day his mental condition was worse, and there was great rapidity of utterance, though no incoherence of speech or confusion of thought, which are so common in traumatic insanities. The patient asserted that he had heard people plotting against him the night before, and manifested plainly unsystematized delusions of persecution. During all of these days there was no fever, and the wound looked perfectly healthy. The emotional disturbance, hallucinations, and restlessness, with the unsystematized

nature of the delusions forced us to a diagnosis of mania. We determined to look again for a possible piece of packing, opening the wound if necessary. The small sinus was enlarged, and I took a probe broken across the middle of the eye, so that two arms were left on the shaft like the prongs of a fork. This I hoped would entangle a bit of gauze if any were left. It was passed between the bone and dura and caused to make a circuit, withdrawing it often to look for an entangled thread. This to our relief finally appeared, having been drawn from the direction of the lateral sinus. A pair of forceps was introduced, the foreign body caught, and a double piece of packing, eight inches in length and an inch in width, withdrawn. The packing was absolutely sweet, contained no pus, and its withdrawal was followed by no discharge. That night the patient slept well, and in the morning presented no excitement or anger whatever, and had lost his persecutory delusions. He went on to complete recovery, and was discharged, cured, twenty-one days after the accident, and eight days after the removal of the gauze.

This case teaches us that no uncertainty should ever exist about the number of pieces of packing introduced into a wound. Only one piece should ever be employed. It would have been better in the case reported, when we found ourselves undecided, to have opened the wound instead of waiting. No harm would have come from opening, while great harm might have come from waiting. This plug of gauze, of such large size, and wedged as it was between the bone and dura, must have exerted great pressure, and yet so tolerant was the brain that ten days passed without a sign of its presence, of which the eye-examination gave no hint. The amount of pressure to which the brain was subjected, without being lashed into complaining, suggests the probable existence of some other factor than pressure when cerebral symptoms accompany depressed fracture. The onset of mania, with delusions, as a result of pressure, and the immediate relief of the symptoms on relief of the pressure, is to me a novel observation. The certainty of our antisepsis was well demonstrated. Had we failed in it disaster would have been almost inevitable.

This case shows further, if any further demonstration is needed, that all compound fractures of the skull, and all fractures with marked depression, require trephining, whether cerebral symptoms are present or not. In this patient cerebral symptoms were entirely absent, and yet there was extensive splintering of the inner table and progressive bleeding between the dura and the bone, which, in a short time, must have caused symptoms of the greatest gravity.

CYSTOTOMY FOR RELIEF OF STONE IN AN INFANT SEVENTEEN MONTHS OF AGE, FOLLOWED BY RAPID RECOVERY.

BY CLAUDIUS H. MASTIN, M.D., LL.D. UNIV. PENNA.,
OF MOBILE, ALA.

As so much has been written during the last few years upon the subject of stone in the bladder, and the various methods adopted for its relief have been so fully and clearly discussed, it seems a work of supererogation even to report an operation for so common an affliction. In this instance, however, the extreme youth of the little patient, together with the rapid recovery which he made after being operated on, induces me to think that it will not be uninteresting to the surgical readers of THE NEWS if I briefly lay before them the details of the case.

The impression commonly exists that stone is more frequently found during the years of childhood than in youth or adult life. Such, however, is not correct, for a careful analysis of facts, together with properly corrected tables of statistics, will prove the contrary. Although stone is often found in children under three years of age —even in tender infancy, as it is in those of the most decrepit old age—still it is not, by any means, more common in childhood than in adult life!

The difficulty of accurately determining the frequency of the disease at different ages has resulted from the want of care exercised by statisticians in distinguishing between *absolute* and *relative* numbers, for it is evident that if we are to ascertain the real proportion of a given disease at different ages, we must include persons not operated on, as well as those that have undergone the operation of cystotomy; having done so, we shall obtain a very different result from that which is furnished by the present existing tables of frequency. For example, if all persons under the age of twenty years were afflicted with any one disease, and all persons over seventy were afflicted with the same complaint, it is evident that the liability would be the same, although the absolute number of persons attacked would be very different. If, then, we construct our tables after this method, including those operated on, as well as those not subjected to any treatment, we shall find that children and young persons are less liable to calculous disorders than has been stated; whilst in reality, from the age of twenty the tendency increases in a remarkable degree to the end of life.

It is not common to find children under the age of three years the victims of calculus, although none is exempt, even from birth to old age. The trouble has been found to exist in intra-uterine life, as is evidenced by the case of Langenbeck, in which he found a calculus in a six months' male fetus; also the case of Stahl (reported in his *Diss. de Morb. fœtuum in Utero Materno*), in which he found a calculus the size of a peach-kernel in an infant of three weeks, the child having suffered great distress from its birth with every act of micturition. Gayer also reports a case which had suffered from birth with all of the symptoms of stone, and which was operated on at twelve years of age, when the stone was found to be so large that it could not be removed until broken up; the fragments were found to weigh ten ounces. Similar cases are reported by various authors who have found stone in young children; but the youngest patient, of which I have any knowledge, which has been subjected to the operation of cystotomy is the case reported by Mr. William Coulson, of London; it was a little boy eighteen months of age upon which he operated, but in the mention of the case he does not state the result of the operation, and I cannot say whether it was or was not successful. Some years ago I was called to a child aged six months, and suffering from retention of urine. Upon introducing a very small gum catheter, I met an obstruction in the membranous urethra, which proved to be due to a calculus about the

size of an ordinary garden pea. I removed it through an incision in the perineum, and the child made a rapid and permanent recovery.

About the middle of June of the present year, during the intense hot spell of weather we were having at that time, a miserable, wizened little child was brought to my office from the adjacent country, for advice and treatment for an attack of "summer complaint," as it was diagnosticated; "entero-colitis" being always prevalent at that season of the year, and hence the mistake.

I found the child straining in its efforts to pass its urine, the genitals chafed and sore, the rectum prolapsed, and all the rational symptoms of calculus present. Under the influence of chloroform, the sound readily detected the stone, and an operation for its removal was advised. In the condition of the child, I did not think it advisable to operate until after a reasonable amount of preparatory treatment had been instituted. To this end, I ordered tepid baths, anodyne enemta, with a solution of sodium bicarbonate and boric acid, to neutralize and render aseptic the urine; this to be combined with a tonic course of the syrup of the iodid of iron, on account of the strumous condition of the child.

The history given was to the end that, last February, for the first time, it was noticed the child had frequent and violent attacks of pain whenever it attempted to pass its urine, and had steadily and increasingly grown worse until it was brought to me in June. The attending physician had resorted to all manner of carminatives, but without avail; and so the parents concluded that none of those "mixtures" would cure the colic, and the child was brought to me as a *dernier ressort*, just as surgeons so frequently receive cases of "obscure disease."

The parents were "well-to-do" farmers, residing in the rural districts, with a family of six or seven children, of which this was the youngest—seventeen months of age. The family history showed no diathesis to which this disease could be traced, if we exclude rheumatic troubles which had been prevalent in some of the ancestors. The mother was deaf, and it was, on that account, difficult to gather a clear history of her family.

After a few days the child had so improved in condition that I thought it best to do the operation, and let it be taken from the city to the fresher air of the country.

On the 19th of August, assisted by Dr. Wm. M. Mastin, who held the staff for me, and other professional friends who were present, the infant being under the influence of chloroform, I performed the median operation and quickly entered the bladder. The stone was very readily found and grasped by the forceps. Not having in my collection a pair of stone-forceps small enough for the case, I was compelled to use a pair of polypus-forceps, having roughened ends; and with this the stone was crushed upon very slight pressure. This being an unavoidable accident, it is not possible for me to give the exact size of the stone, which was removed as a mass of débris. From the bite of the forceps when the stone was first seized, I estimated it to be about as large as a peach-kernel, and the mass of detritus washed out, together with the débris removed by the forceps, would indicate a close approximation to that size. The little fellow very soon reacted from the anesthetic, and within a few hours was as comfortable as he had been previously to the operation. The urine was voided both through the wound and through the natural passage. On the night of the day upon which the operation was performed the child had a temperature of 104° F., which speedily subsided under a small dose of phenacetin, and the next morning he was bright and comfortable. No inflammation followed the operation, and for three days the urine lessened day by day in its passage through the wound until the fourth day, when the incision had so nearly healed that I thought it safe to permit the parents to take him to his home in the country. I have since then heard from them that he has been perfectly relieved and is improving rapidly. The case is an interesting one, both on account of the extreme youth of the patient and the rapidity of recovery after the operation, the patient being discharged on the fourth day, with the wound almost entirely healed and the act of micturition normal.

This case will illustrate the value of "median perineal cystotomy" *in children*, and go to show that it is an easier, safer, and more rapid procedure than any one of the other operations now in vogue.

Uric-acid formations are the most frequent, but, without an analysis, I am inclined to think from the appearance of the fragments that the concretion in this case was made up of ammoniaco-magnesian phosfates.

HOSPITAL NOTE.

THREE CASES OF ANEURISM OF THE AORTA.

German Hospital, Philadelphia.

SERVICE OF ADAM TRAU, M.D.

[Reported by ALFRED HAND, M.D., Resident Physician.]

CASE I. ANEURISM OF THE AORTA; DEATH FROM HEART-FAILURE.

B. S., female, thirty-seven years of age, born in Ireland, married, was admitted July 17, 1893. No family history could be obtained, and all the previous personal history that could be elicited was that four years ago she had had rheumatism, and about six months ago three profuse uterine hemorrhages.

Her present illness dated back six weeks, during three of which she had been in bed. It began with loss of appetite and weakness; then diarrhea and vomiting set in, with pain in the abdomen; she had coughed some, and expectorated some white mucus. There had been neither nose-bleed nor headache.

When admitted she was evidently in a precarious condition. Her face was cyanotic, the pupils were dilated, breathing was labored, and she had a harsh, dry, brassy cough. She was in somewhat of a stupor, but could be roused easily, and would answer questions intelligently. Her temperature was 101.6°, but at evening it came down to normal. The pulse was a typical water-hammer pulse, the rate being 116 per minute. The apex-beat was in the sixth interspace, outside the nipple-line. At the aortic cartilage there were two murmurs—one systolic, transmitted into the carotids, and one diastolic, heard all over the precordia. There was a systolic murmur at the apex transmitted toward the axilla, and failing compensation was diagnosticated. The lungs were clear,

with the exception of moist râles posteriorly. In the left hypochondriac region there was a large area of dulness extending a little below the costal border, while in the right hypochondriac region the dulness was of such slight extent and situated so far toward the mid-axillary line as to suggest a transposition of the liver and the spleen, but after careful examinations it was seen that the liver-area was much shrunken, while the spleen was enlarged.

Throughout the duration of the case there was albuminuria, with hyaline and granular casts.

The daily notes of the case are as follows:

2d day. The diarrhea has ceased, but the pain in the abdomen and vomiting continue; temperature from 99° to 100° F.

3d day. The vomiting has yielded to treatment; patient apparently moribund, but can be aroused for a few seconds at a time; respirations 8, pulse 84, temperature from 99° to 99.8° F.

4th day. Condition same as yesterday, but the abdomen is very tympanitic; expression of the face like that often described as typical of peritonitis; respirations 10, pulse 95, temperature from 99° to 99.6° F.

5th day. The bowels were moved once during the night; distention of the abdomen is excessive; respirations 10, pulse 128, temperature from 100° to 102° F. In the evening, while watching her closely, it was observed that during the pauses of respiration, there could be heard, when standing at the foot of the bed, a to-and-fro sound identical with that heard when a stethoscope was applied over the aortic cartilage. It very much resembled the sound made by a "donkey-engine."

6th day. At 11 A.M. the patient died, with a temperature of 106.8° F.

At the necropsy it was found that the abdominal distention was probably paralytic, as there was neither peritonitis nor obstruction. The liver was contracted, weighing 950 grams. The lobules were prominent, and the surface was very much like that a of placenta. The spleen weighed 500 grams. The kidneys were congested. The heart weighed 400 grams; the valves were not diseased, but the aortic semilunars were rendered incompetent by a dilatation of the orifice due to an aneurism which extended from the origin of the aorta through the transverse arch. The dilatation of the aorta was uniform, and there were no clots; spots of beginning atheroma were numerous.

CASE II. DOUBLE ANEURISM OF THE AORTA, WITH RUPTURE EXTERNALLY.

M. K., male, aged forty-eight years, married, white, born in America, a bricklayer, was admitted October 25, 1892. His history was that three years before he had had a right-sided empyema, which was tapped. A rib was resected, and a drainage-tube inserted until the discharge ceased and the side healed. After this, he was in good health until about six months ago, when he began to be troubled with shortness of breath and painful deglutition. In a short time he noticed a small tumor close to the right border of the sternum. This steadily increased in size, and the difficulty in breathing and swallowing became greater. The appearance and growth of the tumor were marked by no special pain over it. He denied having had syphilis.

On admission he was found to have a pulsating tumor, about the size of a hen's egg, over the third and fourth right costal cartilages, spreading also over the ends of the ribs. There were no heart murmurs, nor any thrill nor bruit over the tumor. The radial pulses were equal, and the pupils regular. Resonance was impaired over the right lung, and the respiratory sounds were feeble, with prolonged expiration. These phenomena, with his former history, raised the question of an *empyema necessitatis*, but owing to the expansile pulsation of the tumor, the pain on swallowing, and the wheezing breathing, the diagnosis was made of aneurism of the ascending arch of the aorta.

For about five months the man's condition remained practically the same, the tumor growing a little larger. The patient was very restless, and could sleep scarcely more than two hours in the twenty-four. At times the tumor would recede somewhat into the chest, and he would then imagine himself better, but the difficulty in breathing and swallowing would be greater.

He left the hospital for two months in the spring of 1893, but came back in June, with the tumor projecting three inches from the chest-wall and extending over an area six by four inches. The overlying skin had ulcerated, and from the surface blood shortly began to ooze. About a week later the rupture came, the stream of blood being at first about a quarter of an inch in diameter and of sufficient force to strike horizontally the wall four feet away. At least twelve minutes elapsed from the first spurt until life was extinct.

The post-mortem examination disclosed an immense aneurism of the ascending arch which had perforated the chest-wall, with erosion of the third and fourth ribs. At its exit from the chest it was constricted like an hour-glass, so that there were two large tumors, one on the inner side and the other on the outer side of the anterior chest-wall. A finger could be introduced through the point of rupture into the outer sac, and a soft clot and the perforation in the chest-wall could be felt. The inner sac could be explored by passing the finger up through the left ventricle into the aorta, which was lined with calcareous plates in its first part. The inner tumor also contained a large, soft clot. On the upper posterior part of the transverse arch was a sacculated aneurism about two inches in extent and an inch deep, containing a large lamellated clot. This aneurism was probably the one which gave rise to the difficulty in breathing and swallowing. The heart was normal, no valvular lesion existing. The left lung was normal, but the right was largely solidified from compression.

CASE III. DOUBLE ANEURISM OF THE AORTA, WITH RUPTURE INTO THE TRACHEA.

C. K., a male, forty-two years of age, unmarried, white, born in Ireland, a laborer, was admitted June 20, 1893. His family history was negative. He himself had never been sick. He contracted gonorrhea and syphilis about sixteen years ago. Last October he began to have sharp pains about the left chest and upon the left side of the face, which were thought to be due to a severe neuralgia. The pains would not be felt while his mind was engaged on his work, but when at rest he would feel them severely. They ceased about four months before admission, and did not trouble him afterward. For three or four weeks before admission he had had a dry

cough, laryngeal, and brassy in character, and a feeling as of something sticking in his throat. He had also been spitting blood for a few days, and exertion would make him short of breath. He had noticed at times unilateral sweating on the left side of the face.

Examination showed equal pupils; unequal radial pulses, the right being normal, the left almost imperceptible; veins around the clavicles dilated; heart-sounds normal; in the left carotid a systolic whiff not heard elsewhere. With both acts of respiration a wheezing sound could be heard at a distance of several feet. Examination of the chest was negative, except that there was dulness over an area with a radius of from an inch to an inch and a half from the left sterno-clavicular articulation. From this, the diagnosis was made of an aneurism of the transverse arch of the aorta, involving the origins of the left common carotid and subclavian, and pressing back on the trachea.

For three weeks the man remained apparently in about the same condition, occasionally spitting a little blood. The fatal hemorrhage came one morning as he was sitting quietly in a chair, after having risen and dressed himself.

The autopsy revealed a large aneurism of the transverse arch of the aorta, equal in size to the heart, beginning just at the origin of the innominate and extending to the descending aorta. It was filled anteriorly with a large lamellated clot, which was softer posteriorly, where there was a channel for the blood-current. The aneurism pressed posteriorly against the trachea, into which it had ruptured through a small opening about an eighth of an inch in diameter and an inch and a half above the bifurcation. On the thoracic aorta, just below the descending arch, there was a sacculated aneurism two and a half inches long and one inch deep, projecting backward. It was lined on the inside with calcareous plates and contained a small clot. The lungs were almost filled with blood, which had flowed down the air-passages, and a large clot occupied the trachea. There were no valvular lesions of the heart.

MEDICAL PROGRESS.

Ureteritis Membranacea.—JAKSCH (*Zeitschr. für klin. Medicin*, xxii, 6; *Practitioner*, No. 302, p. 131) has reported the case of a woman, forty-five years old, who seven years previously suffered from pain in the back and right loin. Soon afterward there appeared pain in the left loin, sometimes attended with vomiting. Two years later a small calculus was passed, with severe colic, referred to the left kidney. Some relief followed this, but attacks of colic, vomiting, muddy urine, and painful micturition occurred at intervals, accompanied occasionally by rigors and fever. The urine was neutral in reaction, contained some albumin, and also some unbranched, translucent, ribbon-like structures about four inches long, arranged spirally. These bodies varied a little in breadth and resembled the similar appearances encountered in the sputum and feces. This resemblance was still closer in that they consisted of mucin and fibrin. Microscopically, they were like Curschmann's spirals, but without the central thread. On the surface could be seen flattened epithelial cells, singly and in groups, such as are found in the bladder and ureter, amorphous masses and crystals of calcium sulfate. Throughout the sediment were scattered amorphous masses composed of calcium carbonate, fine crystals of triple phosphate, well-formed crystals of calcium sulfate, and epithelial cells from the ureter and bladder. Neither cells from the renal tubes nor colorless corpuscles could be found. After rest in bed, the pain in the loin disappeared and the condition of the urine changed in a few days, the spiral formations ceasing to appear and the crystalline forms becoming fewer in number. Sulfuric acid lemonade was administered, and the urine soon became acid, and in a few days the patient was dismissed, much improved.

Varicose Veins in the Arms.—DUTTON (*Lancet*, No. 3648, p. 248) has reported the case of a healthy-looking woman, sixty-five years old, who presented herself on account of an acute attack of eczema of the arms, legs, chest, and abdomen. Until the age of twenty-four the woman had been engaged in housework, doing a good deal of washing. Her work had been rather hard, and washing occasioned swelling and aching pains in the arms. At the age of eighteen, swellings were observed in the arms, which gradually increased in size. Various forms of treatment had been employed, but without avail. Both forearms and the arms for a distance of three inches above the elbow presented soft, painless, movable, superficial knotted masses of various sizes, from the diameter of a pea to that of a walnut. The varicosity did not appear to have attacked the chief superficial veins of the arms, but rather the ramifications of the veins, giving rise to well-defined masses. On vigorous flexion and extension of the forearm the superficial veins swelled to an unusual size. The patient stated that she had often noted the lumps to have a blue appearance, especially after a day at the wash-tub. No definite cause for the condition could be found. There were no signs of pressure; no enlarged glands in the axilla; no signs of intrathoracic tumor or aneurism; and no cardiac lesion. A mild bronchitis existed, but the general health was good. The condition gave rise to no special inconvenience beyond a considerable amount of aching pain after a hard day's work. There was also a considerable degree of varicosity of the veins of the legs and slighter varicosity of the veins of the thigh.

Congenital Fistula of the Upper Lip.—FEURER (*Archiv für klinische Chirugie*, Bd. xlvi, H. 1, p. 35) has reported the case of a man, twenty years old, who from birth presented a fistula of the upper lip, a little to the right of the filtrum. The fistula terminated upon the mucous membrane of the lip, which extended upward to a greater extent than normal. A small amount of slightly turbid fluid resembling saliva continuously escaped in small drops from the external orifice, and upon microscopic examination was found to contain squamous epithelium. The tissues about the fistula seemed a little more dense than usual. A sound introduced into the opening passed upward and somewhat backward, and encountered an obstruction at the level of the lower margin of the right nasal orifice. There was no other deformity of either soft or hard parts. The constant discharge of fluid constituted a source of annoyance and the fistula was removed by way of the mucous surface of the lip. Upon

microscopic examination the lining membrane of the fistula and the surrounding tissue were found to correspond with the tissues of the interior of the mouth.

Enlargement of the Spleen as a Symptom of Chlorosis.—In view of statements that the spleen undergoes no enlargement in cases of chlorosis, CHVOSTEK (*Wiener klinische Wochenschrift*, 1893, No. 27) made some observations upon this point at the second medical clinic of the Vienna General Hospital. In fifty-six cases examined with this end in view it was found that there was demonstrable enlargement of the spleen in twenty-one, usually of moderate degree. That the enlargement was not accidental or due to antecedent conditions not associated with the chlorosis was shown by the fact that in some cases the enlargement subsided in correspondence with the improvement in the general condition.

THERAPEUTIC NOTES.

The Treatment of Goiter by Massage.—SZUMAN (*Münchener medicin. Wochenschr.*, 1893, No. 31, p. 583) has reported the case of a girl, nineteen years old, who had presented a goiter from the age of eleven, and which had progressively increased in size from the period of puberty, at thirteen. For two years there had been, besides, complaint of weakness of the right hand and forearm, with occasional spasm. These symptoms were ascribed to overuse of the hands in sewing and knitting. The patient was also susceptible to catarrhal conditions of the eyes, nose, and throat. The girl's father likewise had a goiter. The patient was well nourished, and presented no lesion of heart or lungs. Both lobes of the thyroid gland were enlarged, and firm in consistence. The condition being believed to be a hyperplastic proliferation of the tissue of the thyroid gland, with increase of the cells of the follicles, massage of the neck was instituted. The patient being seated, the head was inclined slightly backward, and the throat well exposed. The masseur stood behind the patient, and applied the anointed fingers of the two hands in the groove below the lower jaw. The movements were made slowly, synchronously with the respiratory movements, and with varying pressure. The patient was directed to inspire deeply, for the purpose of creating a negative pressure in the thorax. By the aspiration of the thorax and the compression of the veins, the return of the venous blood to the heart was doubly facilitated. The lymphatic circulation was at the same time stimulated. Each sitting occupied a period of ten minutes. Improvement soon set in, and there was shortly an appreciable reduction in the size of the goiter. The patient failed, however, to continue the treatment until the total disappearance of the enlargement.

Poisoning by Chloralose.—LANG (*British Med. Journal*, No. 1700, p. 233) has reported the case of a middle-aged woman who, it was said, had taken an overdose of a soporific. She had been in the habit of taking drugs for sleeplessness, but it could not at the time be learned what drug had been taken or in what quantity. The woman was semi-comatose. She showed signs of irritation on attempts to awaken her, but she could not be roused sufficiently to give an intelligible answer to questions. The face was congested and bluish; the pupils equal and somewhat dilated; the breathing normal; the pulse 60, regular, fairly full, and of high tension; and the skin moist. On a table by the bed were an empty box, which had contained cachets of three grains each of chloralose, and a bottle of syrup of chloral, from which about six drams were missing. The stomach was at once washed out, the fluid returning clear and without odor. An enema of hot coffee was also given. The woman soon became sufficiently conscious to relate that she had taken only three cachets; that she had often taken two, and that on more than one occasion three cachets, without ill-effects. In a little while she was quite well, except for a slight headache. She stated that she had taken hypnotics for many years. Once before she had suffered from a very large dose of chloralose, but quickly recovered after an emetic. On the present occasion she had taken two cachets at 1 A.M., and a third about an hour later. She thought that she had slept for a short time after taking the cachets, then felt ill in an indefinite way, tried to open the door, which was locked, and then fell down and was found there unconscious at 4.30. It is suggested that the untoward symptoms may have been due to rapid absorption from the empty stomach or to impurity in the drug.

For Tuberculosis.—PICOT (*Deutsche med. Wochenschr.*, 1893, No. 30, p. 731) recommends a mixture of guaiacol and iodoform in sterilized olive oil for injection in the treatment of tuberculosis. Every cubic centimeter (16 minims) contains 0.01 (0.15 grain) of iodoform and 0.05 (0.75 grain) of guaiacol. The mixture is clear; its injection occasions no pain, is free from danger, and is reputed to have produced the same results as tuberculin and other agents. It is not considered a panacea for tuberculosis, but an adjunct to fresh air, sustained nutrition, massage, and gymnastics. Its use has been followed by disappearance of the cough, relief from expectoration, and cicatrization of cavities. Fever and night-sweats disappeared, so that curative results were obtained not only in the first, but also in the second stage of the disease.

The Treatment of Hemoptysis.—EKLUND (*Centralbl. f. die gesammte Therap.*, August, 1893, p. 503) maintains that nothing is more dangerous in case of hemoptysis than the common practice of administering cold drinks or bits of ice. The cold causes increase in the bleeding; by irritation of the vagus, cough is induced; and by contraction of the gastric vessels the flow of blood to the lungs is increased. Eklund, therefore, advises the administration of warm and mucilaginous drinks and the application of an ice-bag over the apex of the lung from which the hemorrhage is believed to have taken place. Besides, he directs the taking, three or four times a day, of three grains of quinin sulfate and a grain and a half of ergotin in pill form.

Thryoid-Therapy for the Cachexia Strumipriva.—At a recent meeting of Swiss physicians KOCHER (*Corresp.-bl. für Schweizer Aerzte*, 1893, No. 15, p. 529) presented five cases of the cachexia strumipriva in which treatment with thyroid extract had been followed by results entirely comparable with those obtained in cases of myxedema.

TUBERCULOUS PLEURISY.

INASMUCH as at this time the attention of medical men in all countries is being more than ever attracted to the etiology and pathogenesis of the inflammations of the serous membranes in general and of the pleura in particular, the delivery at Boston of the SHATTUCK Lecture upon the subject of "Tuberculous Pleurisy," by PROFESSOR WILLIAM OSLER,[1] of Baltimore, has come most opportunely. Whereas a few years ago clinicians carried to an extreme the idea that nearly all of the so-called idiopathic pleurisies were tuberculous in origin, at the present time and with the reaction following on the more exact bacteriologic researches, there is a tendency perhaps to ascribe to other microörganisms, *e. g.*, the micrococcus lanceolatus, too imporant an etiologic rôle.

As the field of medical knowledge grows wider, old facts reappear before us disguised in a different garb; we look at objects through tinted spectacles and are prone to give them color and shape from our glasses, only too often to the misrepresentation and distortion of what actually exists. It is at these times that we need the calm and impartial judgment of the experienced observer to correct our visual aberrations, and to prevent us, as the transformation proceeds, from losing sight of old and well-established truths in the rush after new ideas and conceptions.

The SHATTUCK lecturer for 1893 has based his remarks upon the firm foundation of observed facts, and has combined with ample illustration of the different clinical types a careful description of the pathologic changes found in the different forms of tuberculous infection of the pleura.

That a large percentage of cases of pleurisy are definitely tuberculous he shows by an analysis of 101 successive cases of pleurisy that came to autopsy. There were in thirty-two fresh miliary granulations, caseous masses, or diffuse fibro-tuberculous membranes. In eleven of these there were miliary tubercles in the pleura; in eight there was empyema (singularly enough in every instance associated with pneumothorax), and in thirteen the exudation was sero-fibrinous and the pleural leaflets were more or less thickened.

Clinically, the tuberculous pleurisies are divided into two great classes: (1) the acute tuberculous pleurisies, and (2) the subacute and chronic forms. The acute variety includes three distinct groups: (*a*) Acute tuberculous pleurisies that subsequently run a chronic course. In these the onset may be abrupt and resemble a pleurisy *a frigore*, the patient being of good physique and of good family history. The subsequent history alone clears up the case. (*b*) Secondary and terminal acute tuberculous pleurisies in which miliary tubercles appear in the pleura as a result of direct extension, almost always from foci in the lung, and not necessarily associated with general miliary tuberculosis. That not all pleurisies terminating in pulmonary tuberculosis are tuberculous is shown by eleven of the 101 cases in which the causes of the pleurisy were organisms other than the tubercle-bacillus. (*c*) One of the most interesting of all of the forms described is the acute tuberculous suppurative pleurisy, in which there are in the pleura ulceration and suppuration due to the tubercle-bacillus. These cases have actually been looked upon as instances of mixed infection with pyogenic organisms, but in a case of multiple abscesses in the pleura in a young girl, reported by the lecturer, cultures made from the pus remained sterile, while cover-slip preparations showed an extraordinarily large number of tubercle-bacilli. This favors the theory that the tubercle-bacillus sometimes acts as a pyogenic organism, but until further examples are recorded it will probably be safe to still regard such cases as instances of mixed infection, the sterile

[1] Boston Med. and Surg. Journ., 1893, Nos. 3, 4, 5, and 6.

cultures perhaps being accounted for by the death of the pyogenic bacteria before the death of the patient. In any case this type of acute tuberculous pleurisy must remain a most interesting and important one.

Turning to the subacute and chronic forms, DR. OSLER divides these also into three groups: (*a*) those with a sero-fibrinous effusion, which may be primary (when they are prone to be particularly insidious and are likely to be overlooked) or secondary to lung-tuberculosis, when they are as a rule easily diagnosticated; (*b*) those with a purulent exudate, when the onset is subacute, and the course is chronic and latent, usually associated with pneumothorax; and (*c*) the chronic tuberculous adhesive pleurisies, the special feature in these being the extensive, sometimes enormous, thickening of both layers of the pleura.

Attention is drawn to those less usual cases of general tuberculosis of the serous membranes that present a fairly distinctive clinical type, in which the infection attacks the serous membranes one after another, or in which the pleura and peritoneum, and at times the pericardium, may be affected almost simultaneously. The clinical classification of BOULLAND is closely followed here, and the obscurity of the affection, together with the protracted course, with periods of improvement and often with little or no fever, are dwelt upon. All of the clinical types are illustrated by protocols of cases that have been under the lecturer's observation.

Passing on to the general pathology of the tuberculous pleurisies, DR. OSLER deals at considerable length with the avenues of infection, describing the different routes by which the tubercle-bacilli gain entrance to the pleura. The majority of cases, it would seem, arise through direct infection from the lung, a superficial focus there extending directly to the pleura. In very many cases, however, including those of primary tuberculous pleurisy, the bacilli reach the pleura through the lymph-channels, by inhalation and deposition on the bronchial mucous membrane and transportation along with dust-particles through the interstitial lymph-spaces, or by infection through the lymph-channels from the neck (scrofulous glands, carious bones), or by extension upward from the peritoneum to the diaphragmatic pleura.

While in some cases the diagnosis is easy, in many it is extremely difficult to decide that a given pleural exudate is positively tuberculous—a fact which is not surprising when we consider the very diverse clinical variations met with. The appearance of the individual, his previous history and that of his family, the mode of onset, the course of the affection, and the character of the exudate—all have to be carefully considered, but often none of them may even be suggestive—or when they lead to suspicion may be misleading. We are recommended to carefully inspect the different groups of lymph-glands contiguous to the pleura, and to examine the expectoration of the patient repeatedly for tubercle-bacilli. The bacteriologic examination of the exudate, which has been so much insisted upon of late, is fully dealt with, and when inoculations into ordinary culture-media remain sterile there is presumptive evidence in favor of a tuberculous pleurisy. The examination of cover-slip preparations, except in the case of a purulent exudate, rarely permits the demonstration of tubercle-bacilli. The inoculation of guinea-pigs with portions of the exudate probably offers the best chance of determining their presence or absence. In cases of empyema a tuberculous process is often complicated by infection with ordinary pyogenic organisms.

The diagnostic value of injections of tuberculin is regarded as very uncertain, and a case is reported in which a marked reaction followed such an injection, the autopsy subsequently showing the case to have been carcinomatous and not tuberculous at all. The diagnosis in the chronic forms, with sero-fibrinous exudate and thickening of the pleura, in which there is persistent flatness at the base of the lung, is peculiarly difficult, but the recurrence of an effusion in spite of frequent aspirations should make us suspect a tuberculous process.

The limits of this article will not permit us to more than mention the therapeutic suggestions laid down. The indications are twofold: (1) to limit and control the exudate and to endeavor to promote absorption, and (2) to improve the general condition of the patient and increase his powers of resistance, in order if possible to bring about healing of the tuberculous lesions. After the acute stage is over, during which rest and dry diet are desirable, repeated aspiration being resorted to if necessary, we are to endeavor to promote nutrition by careful feeding, a well-ordered life, perhaps by a change of climate, and by the exhibition of suitable tonics. Pulmonary gymnastics may be of value when there is retraction of the chest. The purulent cases, in which the condition of the patient permits, are of course to

be turned over to the surgeon for evacuation and thorough drainage. The lecture is brought to a close with a quotation from SIR ANDREW CLARK: "When we have a patient with basic fibrinous pleurisy let us hold him fast, restrict his freedom, and treat him carefully until every remnant of it is gone."

THE PROGRESS OF CREMATION.

CREMATION is like an epicure's dish, which must be tasted often before it can be liked, and the first taste thereof requires fortitude and high-thinking. Cremation has been opposed quite needlessly as a violation of law, of custom, of religion, etc. It deserves none of these censures, however, and is unmistakably growing into favor in Europe and America. In Germany,[1] for instance, in populous countries in particular, it is more frequently practised than elsewhere, perhaps from necessity. In Gotha alone during the past fifteen years there have been nearly twelve hundred cremations. It is found to be a decent, honorable, and salubrious method of disposing of the dead. It is easy and not expensive. Nor is this all. The usages of the churches, the rites that make up a Christian's obsequies, are not neglected. The burial service is commonly read; and we can scarcely resist the evidence that in the eyes of the Church there can be nothing impious in this mode of sepulture.

We are indebted to MR. AUBREY RICHARDSON for the ability to make these statements with a clear conscience. In an excellent little book recently published and entitled *The Law of Cremation*,[2] he furnishes ample proof of what has just been said. What, for example, can be more satisfactory than the following passage describing the method of procedure at Gotha: "The crematorium, which is constructed after the design of HERR SIEMENS, Engineer of Dresden (*regenerative system* with gas-furnace), stands in the new cemetery at Gotha. All the apparatus is situated underground, beneath the chapel floor, and is so arranged that the coffins can be lowered gradually into the receiving-chamber during the reading of the burial service, and mechanically passed on into the furnace itself" (p. 135). Such obsequies are not unpleasing, and we hardly think that any imagination will startle at these details.

The selection of the site of a crematory is a point of the utmost consequence to the public. For, although the combustion of a corpse may be accomplished in a rapid, inoffensive manner, as far as disagreeable sights and smells are concerned, yet this would not always be so if no proper rules were formulated and observed in so important a matter; and the proximity of a crematory can hardly be contemplated with any other feeling than aversion. The sixty-fifth article of the Italian Burial Law, which directs "that crematory furnaces must not be erected without the walls of public cemeteries," is wisely followed by the law or custom of most countries.[1]

What are the objections to cremation as a form of burial? We consider the reasons *against* it rather than the reasons *for* it, because the latter are too obvious to need discussion. The chief objection is that mankind in Christian countries has for centuries preferred to bury its dead. CONSTANTINE strongly condemned the practice of cremation on religious grounds. NAPOLEON rejected it after mature deliberation. The fact that men have a prejudice in favor of burial, a prejudice to which they adhere with passionate hereditary instinct, is a positive objection to cremation. A scruple, regarded as pious and honorable, is no light thing. Men who are under the influence of this scruple will always find in cremation something unspeakably revolting, some taint as of impropriety or barbarism, some want of respect for the dead and for the religious feelings of the living. The practice, they will say, has been more frequent with barbarous than with civilized races. The savage and superstitious Carthaginians adopted it. It was an immemorial custom with the North American Indians; so, too, with the Druids. The great races of antiquity condemned it. The Jews and Egyptians practised it not at all; the Greeks but seldom.

Such prejudices, indeed, are wholly groundless. Yet, as long as public sentiment is of this mind cremation cannot be popular, cannot certainly be enforced by law.

The objections so frequently urged against cremation—its difficulty and expense, can scarcely be maintained now. In fact, the practice is not more difficult and more expensive than ordinary

[1] Prussia is an exception.

[2] The Law of Cremation, by Aubrey Richardson, Solicitor. London: Reeves & Turner, 1893.

Mr. Aubrey Richardson is a son of the admirable writer and physician, Dr. Benjamin Ward Richardson, F.R.S.

[1] Op. cit., pp. 104, 105.

burial. The United States Cremation Company (Limited), whose regulations deserve to be carefully studied, requires but an advance of $35 for this purpose. A more important objection is that cremation may offer opportunities of destroying the evidence of crime. This objection, we are convinced, betrays a complete ignorance of the legal procedure of a cremation. For the law on this subject, the police regulations that everyone must observe where cremation is legally recognized, are much more efficient safeguards against crime and the concealment of crime than the regulations of ordinary burials. In England, where the practice of cremation is merely tolerated as not illegal, an enormous number of persons are annually buried without any medical certificate or inquiry whatever. In 1885 the number of these persons was 18,146; in 1886, 18,322; in 1889, 15,100. The number of exhumations ordered by the courts to detect poison has been less than one yearly. If cremation were universally adopted under the rules of the Woking Crematory, or better still of the Crematory Society of Zurich, such a state of things would be impossible.

The gist of the whole dispute between the advocates of cremation and their opponents seems to us this: Is cremation necessary in order to prevent the bodies of the dead from poisoning the living, and if so, when is it necessary? For obviously it is not needed in all cases and under all circumstances. In a country that supports but one person to the square mile it is not necessary. We should not think of enforcing it in the Highlands of Scotland, in Iceland and Scandinavia, or in Libya. What is the use of burning a dead body where there is no risk of contagion? The dead on the battlefield and the victims of a pestilence ought, we think, to be buried. When the population may be three hundred to the square mile we can easily imagine that cremation would be an admirable precaution. The purpose of cremation is, of course, to reduce a corpse to absolutely harmless ashes. The rapidity of the process, its completeness, too, recommends it. But though the combustion of a corpse is, beyond comparison, more rapid than its decay, yet the whole procedure of cremation is more complicated and requires more time than burial. Burial, indeed, is the most expeditious mode of sepulture. Under the law, a cremation can scarcely take place in less than two days, while a burial may be an affair of but a single hour. The point of chief importance is to remove the corpse as a source of contagion as soon as possible. In what way is this better accomplished than by means of burial? But it will be said that the speedy removal of the corpse, though a stern necessity in times of epidemic and something to be thankful for at all times, is not sufficient, as the risk of contagion is always present until the remains are wholly incorporated in earth.

Whether the interment of the whole corpse is so noxious a procedure admits of reasonable doubt. A writer in the *Annales d'Hygiene*, of recent date, infers from the results of excavations in Europe that the old method of burying in graves and trenches is, after all, the best and safest way of disposing of the dead. The evidence shows that infectious diseases are not engendered in those places. The earth purifies like fire. A cemetery properly situated is not a source of disease and contagion. A cemetery is objectionable when, as in very populous districts, it occupies a disproportionate amount of space or too little space. The latter condition is by far the worst. For the vast cemeteries, so common now, are merely a needless encroachment upon the living, but a cemetery too small is so frequently tenanted as to become a vile and contagious spot.

We revert to a consideration, often hinted at in the course of this paper, namely, that cremation should be adopted wherever it is a plain necessity. It is necessary whenever cemeteries are objectionable for reasons just given; whenever, as in Germany they become (as COLERIDGE expressed it) places not more dangerous to health than to morality; and finally, it may be said that cremation is intrinsically better than burial, for, though burial is seldom dangerous, cremation is never so; though burial is expeditious, cremation may be accomplished at least as rapidly; and the procedure of a cremation is even more decorous, is directed by even wiser legislation than the procedure of burial.

THE FIRST PAN-AMERICAN MEDICAL CONGRESS.

As these lines are being written the First Pan-American Medical Congress, with its twenty-two sections, is in session at Washington. From the reports that we have thus far been able to gather the meeting promises to be a perfect success, even beyond the most sanguine expectations of its organizers. Of the fruit that shall be borne it is of course yet too early to speak, but naught but good can be the outcome. Too much praise cannot be given to

those upon whom devolved the onerous duty of organization, who have labored so earnestly and so faithfully, and who must find in the success of their efforts a source of immeasurable gratification.

EDITORIAL COMMENTS.

An Impartial Judgment of Homeopathy.—The following quotation from the *Wiener medicinische Presse*, 1893, No. 30, p. 1202, must certainly be admitted as a dispassionate and judicial statement of the position of homeopathy, written without heat or partisanship, but in a spirit of actual fairness and honesty :

"The 2d of July marked the fiftieth anniversary of the death of Samuel Hahnemann, the founder of the 'homeopathic method of treatment.' In an article dedicated to the memory of Hahnemann, by L. Buechner, the distinguished author of *Force and Matter*, after an acknowledgment of Hahnemann's intellectual ability, it is stated that homeopathy is a suitable method of treatment for rich, indolent, nervous, egotistic patients, or such as have a dread of medicines, whose ills, great or small, disappear spontaneously, without medical treatment or with any form of treatment, and with whom the imagination acts as an important adjunct to the processes of nature. Homeopathy will therefore probably never entirely disappear, and is not to be denied a certain amount of credit, partly positive, partly negative. The patient believes that he will be helped by homeopathic remedies, and is really helped—partly in consequence of belief and partly by awaiting the natural outcome of his ailment during the continuance of the homeopathic treatment.

"In the hands of unprofessional persons prescribing their own homeopathic remedies, or in the hands of uneducated quacks, the method is capable of much harm, which it has doubtlessly accomplished in innumerable instances."

This judgment may not apply to the self-styled homeopathist who finds in sectarianism only a means to selfish ends. For him more drastic measures may be necessary; but if there be reputable men among so-called homeopathists, it is time for them to throw off their masks and repudiate a designation that among the discriminating has become a synonym for duplicity and false pretence.

Rhus Toxicodendron.—Apropos of the comment in THE NEWS of August 26, 1893, p. 248, we have received from Dr. John Aulde, of Philadelphia, a reprint of an interesting communication made by him to the *Medical and Surgical Reporter* for September 27, 1890, upon "The Use of Rhus Toxicodendron." Therein he points out the pharmacology, the properties, the physiologic effects, and the therapeutic applications of rhus. He advises the use of a tincture made according to the directions of the U. S. Pharmacopeia, from the fresh leaves gathered during the period of efflorescence. The dose ordinarily should not exceed half a drop three times daily. The drug is said to act as a cerebral stimulant and at the same time to possess the property of allaying the irritability of the sensory nerves. It is regarded as possessing also properties allied to those of an antiseptic, and has been found to act as an eliminant. The effects of lethal doses are said to be best antagonized by the exhibition of some preparation of lead. Rhus has been especially employed in the large and ill-defined group of diseases that are designated by the qualification chronic rheumatic, including arthralgias, myalgias, lumbago, wryneck, neuralgias, and other painful affections of uncertain nature. Hemorrhoids, varicose veins, and chronic cystitis, it is said, are usually promptly relieved by the exhibition of this drug. "In the treatment of erysipelas small doses seem to arrest the tendency of the eruption to spread, while the fierce character of the inflammation is subdued and the temperature and pulse fall. . . The chronic varieties of skin-diseases respond most readily to this drug, and especially the scaly forms; but it is useful in all cases dependent upon an unhealthy condition of the digestive tract." Certainly a drug that has such valuable properties and such a useful field of employment as are claimed for rhus should receive more extended application than has hitherto been given it.

The Noisome Noise of Unmusical Music.—THE NEWS is delighted with the responsive Amen ! in many lay and medical journals and from personal correspondents as regards its protest against the brutality of the noise-makers. It is a pity that we should end with protest only, and that legislative and police restriction cannot be made effective. Let everybody appeal personally and by letter to the proper administrative authorities and demand that illegal noises shall be stopped, and that those that are not absolutely forbidden shall be lessened. Medical societies should act as bodies and through committees to abate these nuisances. The hours for sleep should be kept quiet for the thousands of sleepers and and not monopolized by the half-dozen brawlers and howlers. There seems to be a tacit understanding on the part of the police that anything that a South-sea Islander or an Oriental would call "music" must be sacred, no matter how execrable and ear-splitting the din or the bawling. The police of Philadelphia would not think of stopping a crew of drunken singing rowdies, a darkey band, a French-harp fiend, an organ-grinder, or an accordion monomaniac from committing his crimes against health, no matter if the iniquities are carried out in what should be the stillness of Sunday or of the night. The air-beaters and ear-bangers have it all their own way, and if a lot of well-to-do folk meet together to eat and chat, they set a worthy example by having a band to scrape and blow musical sounds that not a single diner listens to for a second and which forces him to roar and bellow at the top of his voice to make his neighbor six inches away hear a spoken word. "What you talk about is music, but what you like is noise," said a wise man to his pupil, and it is true here and to-day.

Mental Suffering as an Element of Damages.—We speak of physical suffering, and of effect upon physical powers, but no one would claim for a moment that the two things are identical. Physical suffering may exist and be an element of damage, and yet there be no impairment of the physical power to earn money; and the physical power to earn money may be greatly impaired and an element for substantial damage, and yet there may exist

no suffering whatever. True, the two, for a time, at least, after an injury are usually present together, but there is no necessary connection between them. The same is true of the mental domain. Mental suffering may exist, and the mental powers—that is, the power to exercise the mental faculties for the purpose of earning money or otherwise—be in no manner affected. On the other hand, the power to thus exercise the mental faculties may be impaired or destroyed, and yet there may be no mental pain. Mental suffering is a proper element of damages, and the impairment of mental faculties is also a proper element, when claimed and proved. So holds the Supreme Court of North Dakota in Comaskey *v.* Northern Pacific R. R. Co. (55, Northwestern Reporter, 732). But it says that in an action to recover for personal injuries, when there is no claim in the complaint or in the evidence that the mental powers of the person suing were in any manner impaired by the injury, it is error for the trial-court to instruct the jury that in estimating the damages that they may take into account the effect of the injury upon the mental powers.

The Restoration of Hearing to the Deaf.—By analogy with the good results obtained in other forms of loss of function from disuse, it seems reasonable to hope that in some cases of deaf-mutism it may be possible to restore some degree of hearing, as well as of speech, by means of acoustic exercises. The idea is not a new one, and was long ago acted on. Upon this line of thought URBANTSCHITSCH (*Wiener klinische Wochenschrift*, 1893, No. 29, p. 525) has made observations upon a number of deaf-mutes who by methodic exercise not only regained the faculty of hearing vowel-sounds, but also acquired the ability to hear and to repeat whole sentences. Some of the cases, upon first examination, appeared totally deaf, hearing neither through the air nor through the bones of the skull. The restoration of hearing to an apparently totally deaf person obviously implies that there cannot have been actual deafness, but only an inability to properly interpret acoustic impressions. A development of the auditory sense was equally a result of the exercises, sounds that were previously not at all heard being readily recognized and differentiated. The exercises consisted in indicating by sign or symbol the sound to be made or the letter to be spoken. As at times they proved quite fatiguing, they were at first given for half an hour, daily, subsequently for an hour, preferably without the use of a speaking-trumpet.

Every Man His Own Physician seems to be the motto of the self-druggers, a brilliant company that is wonderfully increasing in numbers. Nowadays every toper knows all about chloral or carries in his vest-pocket his own supply of "bromidia." Every soda-water fizz-fountain has its array of prepared drugs ready for customers who habitually ask for the peculiar "tonic," or "sedative," or "corrective" that they know so well about. The accommodating druggist or fizz-water drawer will supply any possible defects of knowledge (or ignorance) on the part of the self-prescriber and recommend anti-pains or germicides galore, for a few cents, to be washed down with the universal fizz-water. Every hysterical woman has her very peculiar "smelling-salts," her pain-deadener, nerve-sedative, or headache cure, self-prescribed, *pro re nata* and *quantum libet* or *sufficit*. Sometimes the *quantum* is a little more than "*sufficit*," as in a recent case, in which, to "sober up," too much "bromidia" was taken, and the result was a sober-down into the grave. This reckless selling of dangerous drugs to Thomas, Richard, and Henry should be stopped. Medicine of the people, for the people, and by the people, is a dangerous sort of democracy.

The Identity of the Streptococcus Pyogenes and the Streptococcus of Erysipelas.—The morphologic resemblance between the pyogenic streptococci and the streptococci of erysipelas early suggested the possibility of their identity, but it was difficult to furnish the proof to substantiate such a belief. A case recently reported by KNORR (*Berliner klinische Wochenschrift*, 1893, No. 29, p. 699), of Berlin, would seem to furnish the necessary demonstration. The case was one in which in the sequence of an injury to the foot an abscess developed upon the thigh, and in the contents of which pyogenic streptococci were found. At a later date an area of erysipelas developed in the sacral region at the site of a small bedsore. The case terminated fatally, and after death examination of a bit of skin removed with suitable precautions from the erysipelatous area, disclosed the presence of streptococci that both in appearance and in behavior in cultures and upon inoculation were identical with those obtained from the abscess, while similar organisms could not be found in the healthy skin.

The New Pharmacopeia has been issued, and should be in the hands of every physician and pharmacist before the date at which it becomes official—January 1, 1894. We present elsewhere a brief account of some of the changes principally interesting to physicians. Pharmacists will find much more to study, perhaps to criticise. The Committee of Revision requests criticism and suggestion, which should be addressed to Dr. C. C. Rice, Chairman, Bellevue Hospital, New York. The work is a decided advance upon all previous publications, and has been brought up to the latest date possible while passing through the press. The Committee cannot be too highly praised for its promptitude and efficiency.

Onychophagy is the name given by a French physician to the morbid habit of nail-biting. He finds it very common among French school-girls—61 out of 207 in one school. Are the deformed finger-ends and nails so commonly seen a result of the custom?

REVIEWS.

THE PHARMACOPEIA OF THE UNITED STATES OF AMERICA. Seventh Decennial Revision (1890). By Authority of the National Convention for Revising the Pharmacopeia, held at Washington, A. D. 1890. Official from January 1, 1894. Published by the Committee of Revision. Philadelphia: J. B. Lippincott Company. Agents: P. Blakiston, Son & Company. 1893.

THE new Pharmacopeia is a thoroughly good book. The Committee of Revision and the printers have both done well their respective shares of the work of prepara-

tion and issuance of the new standard, and they, as well as the profession, are to be congratulated alike on the accuracy and the neat appearance of the official volume. The preface gives clearly and succinctly an account of the principles guiding the Committee in its work, and indicates what changes have been made in the text. Lists of changes of titles and of articles added and dropped, and the various tables of chemic data, add to the usefulness of the work. The determination not to admit articles that can only be made by a patented process, or names in which a proprietary right is claimed, shows that in any truly representative medical or pharmaceutic body right principles still prevail. The metric system has been adopted in the text, solids being prescribed by weight, and liquids, except in certain instances, by measure. The substitution of the ordinary chemic nomenclature for the cumbrous and obsolete system of former Pharmacopeias, *e.g.*, "sodium phosphate," instead of "phosphate of sodium," is to be commended. The Committee has done wisely, however, in retaining the respective adjectives in the Latin and English titles of mild mercurous chlorid and corrosive mercuric chlorid, yellow mercurous iodid and red mercuric iodid, etc. The change from *green* to *yellow* in designating the protiodid is an improvement without danger. We regret that the Committee did not decide to adopt the new spelling of chemic names advised by the American Association for the Advancement of Science. Some orthographic changes have, however, been made. Arsenium becomes arsenum; aluminium becomes aluminum, and their derivatives are correspondingly altered in Latin and English. Creasotum is changed to creosotum. The terminal "e" is retained in the spelling of oxids, chlorids, chlorin, iodin, etc., and in the names of alkaloids, to distinguish them from the so-called neutral principles. This is a disappointment to us.

In addition, erythroxylon becomes coca, brayera becomes cusso in Latin and kousso in English, thus making the ordinary and official names the same. Other changes of official titles indicate change or greater strictness in the preparation. Thus, æther fortior becomes æther, and chloroformum purificatum becomes chloroformum, the dropping of the adjective indicating that the commercial preparation is no longer recognized in either instance. Aloë becomes aloë socotrina, and aloë barbadensis is added. Extractum belladonnæ foliorum alcoholicum and extractum belladonnæ radicis fluidum replace the shorter titles of 1880. Gossypium becomes gossypium purificatum. Viburnum becomes viburnum prunifolium, and viburnum opulus is added. The entire class of abstracts is dropped; wisely, we think. Of the mixtures not dropped, that of ammonium and iron acetate becomes a solution (Latin, *Liquor*), and those of ammoniacum, almond, asafetida, and chloroform become emulsions (Latin, *Emulsa* [*um*]). While adding this class (emulsions), an official emulsion of cod-liver oil would have been in place. Aqua hydrogenii dioxidi becomes official as a 3 per cent. (about ten-volume) solution, slightly acid. The penultimate *i* should have been dropped, as in arsenum and aluminum.

Among other important additions are acetanilidum, aloinum, aspidosperma, cocainæ hydrochloras, convallaria, strophanthus, salol, naphthol, hyoscinæ hydrobromas, eucalyptol, pepsinum (digestive strength 1 : 3000), pancreatinum, petrolatum liquidum, rhamnus purshiana, sodii nitris, spiritus glonoini, sparteinæ sulphas, and the salts of strontium. In all, eighty-eight new articles have been introduced, and ninety of those previously official have been dismissed. The word official, too, is recognized in place of officinal, a reform long contended for by Bartholow.

We regret not to see ethyl iodid, bromoform, trichloracetic acid, ozonic ether, quinin and urea hydrochlorate, guaiacol and its salts, naphthol benzoate, quinin salicylate, cinchonidin salicylate, and bismuth salicylate among the additions. An official preparation of peptones, an official preparation of carica papaya, an official albuminate of iron, an official preparation containing iron and a salicylate, an official syrup of hypophosphites containing strychnin, are desiderata not yet supplied.

In conclusion, we must again express to Dr. Rice and his associates our high appreciation of the thoroughness and scientific accuracy of their work—a work of which, while all of us reap the benefit, but few realize the labor.

A Manual of Diseases of the Ear. By George P. Field, M.R.C.S., Aural Surgeon and Lecturer on Aural Surgery, St. Mary's Hospital Medical School, London. 8vo, pp. 391. Philadelphia: Lea Brothers & Co., 1893.

The most apparent merit in this volume is the excellent colored plates illustrating the normal and pathologic appearances of the aural fundus. All are shown as viewed through the speculum, with the latter in its proper position, and are about the best that have yet appeared in any book on the ear, and almost the first seen by the reviewer which are of real value to students.

The anatomy, physiology, and physical examination of the organ of hearing are ably discussed in the earlier chapters of the work, the remaining sixteen sections being devoted to the diseases of the ear.

Osseous tumors of the meatus are very fully discussed, and the best methods of operation ably described—the chapter being one of the best on this subject; a large number of cases are reported in detail.

The weakest part of the book is that devoted to catarrhal and suppurative inflammation of the middle ear, the treatment advised being, for the most part, very old-fashioned, crude, and not well suited to American patients, however it may act on an English clientèle.

Aural polypi are well described, and especially well illustrated, and the treatment recommended is well up to date.

The therapeutics of tinnitus aurium is treated of in less than two pages, and it is not equal in value to the major part of the volume.

Taken as a whole, the book well deserves a prominent place in the library of every aurist, and will be found particularly valuable by the young student in aural pathology and diagnosis. As is the case with so many works written by European specialists, the treatment advised must, however, be largely modified by American methods in order to secure the best results in our climate.

STRICTURE OF THE URETHRA. By G. FRANK LYDSTON, M.D., Professor of the Surgical Diseases of the Genito-urinary Organs and Syphilology in the Chicago College of Physicians and Surgeons, etc. Chicago: The W. T. Keener Co., 1893.

THIS volume is based on a course of class-room lectures delivered by the author, the aim having been to produce a practical work rather than one complete in the history of the many phases through which urethral surgery has advanced to its present position. It is designed for the general practitioner and student rather than for the andrologist.

The first chapter is devoted to a study of the anatomy of the urethra, which is essential to a clear understanding of the pathologic conditions that affect this structure. The author dwells with commendable emphasis on the the necessity for asepsis in urethral work. There is no doubt but that in the past lives have been lost by indifference in this particular, but this should not occur now that the value of "surgical" cleanliness is so fully established. The subjects of spasmodic, inflammatory, and congestive stricture have been simplified by considering them usually as complications of organic stricture. These the author calls *plus conditions;* they must be removed by appropriate measures before the treatment of the true stricture can be satisfactorily continued. We think that Dr. Lydston gives a very fair estimate of the value of electrolysis in the treatment of urethral stricture. He has demonstrated his thorough familiarity with the subject upon which he writes. The treatment recommended in the different varieties of stricture is in accord with that taught by the foremost of our conservative specialists, and may be followed with the confidence that it is the best at our command in the present state of knowledge. The book cannot fail to be of value to those engaged in this line of work. A few typographic errors and a mistake in numbering some of the cuts have escaped the proof-reader, but these do not detract from the merit of the text.

CORRESPONDENCE.

IMPROVED PLASTER-OF-PARIS JACKET.

To the Editor of THE MEDICAL NEWS,

SIR: In THE NEWS of January 21, 1893, p. 70, there appears an article under the caption of "Plaster-of-Paris in Orthopedics," by Dr. A. J. Steele. In speaking of the use of plaster in the treatment of Pott's disease, Dr. Steele employs the following language:

"Usually the plaster jacket is made to extend above not higher than the axillæ; but if the disease is in the cervical or upper dorsal region, more thorough support can be obtained by carrying the bandage above the shoulders, like a vest. *I cannot say whether or not I was the first to adopt this plan, now some twelve years since* [italics mine], but certainly support for three or four additional vertebræ can thus be had; and with the disease in the cervical region the bandage has been carried still higher, up the back of the neck and around the head. To additionally strengthen the jacket I fortify it with strips of galvanized-wire gauze, the size and strength of the strips depending upon the age of the patient; the corners are cut off and the edges bound with sticking-plaster. The plaster is better incorporated with the gauze than with perforated tin."

It is with the intention of relieving Dr. Steele from the doubt as to whether he or someone else was "the first to adopt this plan," as well as for the benefit of those of your readers who are interested in this subject, that I make this communication.

I quote from a paper of mine published in the *St. Louis Courier of Medicine*, December, 1880, under the title "Improved Plaster-of-Paris Jacket, or 'Cuirasse' for Posterior Spinal Curvature in the Middle and Upper Dorsal Regions":

"In 1876, while attending Mrs. W., she asked me whether I could not do something for her son (six years old) who was the subject of posterior spinal curvature (2d to 6th vertebra) and who had been for some time under the care of various physicians and surgeons without receiving much, if any, benefit." As this was out of my line of practice (gynecology) I recommended Dr. Louis Bauer, the well-known orthopedist, who, after exhausting every known means for eighteen months stated to me on May 3, 1878, that unless some new means was devised the treatment would prove to be a failure. This, to my great disappointment, I had observed long before, and explained to Dr. Bauer the principle of the cuirasse that I had mentally devised for this patient while observing the failures and imperfections of the apparatus tried, including Sayre's. The plan was adopted and the apparatus applied with success.

"The 'cuirasse,' or vest, as Dr. A. J. Steele calls it, may be made, like Sayre's jacket, of other material, or of plaster-of-Paris rollers and strips of tin or veneering. The patient being suspended and provided with a thin, tightly-fitting undershirt, as directed by Dr. Louis A. Sayre, rolls of cotton or folded cloth are stitched to the undershirt on either side of the curvature. The bandage is applied first by a few circular turns around the chest, sufficiently tight to prevent the respiratory motion of the ribs, then obliquely across the shoulders so as to immobilize the clavicles and scapulæ. This is continued by means of an occasional reverse of the roller until the entire chest is covered, reaching down behind to the twelfth dorsal vertebra, from thence along the lower border of the ribs and costal cartilages to the inferior extremity of the sternum, and above from the vertebra prominens, along both sides of the neck to the upper border of the sternum in front, thus covering the thorax completely as by a shell. This bandage, when tightly applied and allowed to harden before the suspension is interrupted, will keep up every advantage gained by the suspension, since on account of its tight application it sustains the chest rigidly in the shape thus given to it. Respiration is henceforth altogether abdominal. The diseased vertebræ are free from pressure, and undisturbed by the motions of the loins and head, and by the fixation of the shoulder-blades and clavicles, of those of the upper extremities. They are also pressed as nearly as possible in a line with their healthy neighbors without pressure on the prominent spines, because of the lateral pads; their healthy parts sustain the weight, while the diseased bodies of the vertebræ are left free and unencumbered. Thus the 'cuirasse' is to

the chest as solid and complete a splint as ever was applied to any single fractured bone.

"The necessary exercise for the maintenance of the general health is greatly favored by it on account of the perfect freedom of all the customary motions. When the patient is dressed it is so nearly invisible that none but those initiated will notice its presence. . . . .

"A new bandage was applied July 12, 1878, but in consequence of the inferior quality of plaster accidentally used, the apparatus soon crumbled, and accordingly a new one was substituted on August 2d. Dr. Bauer being out of the city at the time, Dr. A. J. Steele was called in for that purpose, and the apparatus now for the third time successfully applied. As the child was to be removed for the hot season to the North, his parents desired that the splint should be fixed so that they could easily remove it, should necessity require it. To meet their wish, I cut it open over one (the left) shoulder and down on the same side, breaking the plaster with a dull knife and hammer by gentle blows on the opposite shoulder and side, so as to make the remaining cloth act as a hinge, then separating the cut edges made the boy, his right arm extended horizontally, step out of the shell to the left. Along the cut edge, over the side and shoulder I had buckles and straps attached."

As this device has certainly done much good in an otherwise almost incurable class of cases, I may be excused for objecting that others should claim its invention.

Respectfully,

Eug. C. Gehrung.

St. Louis, Mo.

PLASTER JACKETS.

To the Editor of The Medical News,

Sir: In reply to the communication of Dr. Eugene C. Gehrung, the advance sheets of which you have kindly submitted to me, I would say that I gladly accord to the doctor his claim of originality and priority in the splint which he calls the "cuirasse."

When I made the remark which in the quotation is italicized, I did not have in mind the "cuirasse," which finds its limit below with the line of the ribs and sternum, but to the long jacket, which extends downward as far as the flexure of the thighs, and which does include the abdomen—an entirely different appliance from the former—one covering the chest only, and the other the whole body. It was this long splint also I had reference to in my article read before the Missouri State Medical Association, May 22, 1878, and published in its *Transactions*, p. 18, from which I quote: "With the disease in the upper dorsal region, additional support may be gained by passing the bandage (plaster) obliquely over the shoulder"—which statement, as far as I know, is the earliest published reference to the matter.

In my paper on the "Uses of Plaster" I did not make mention of the gypsum "cuirasse," but I would gladly do so now if not too intrusive. For several years I faithfully tried the short "cuirasse" in upper dorsal disease, but being greatly disappointed in the results, I discontinued its use and have not employed it for many years.

I especially remember one case of Pott's disease in the upper dorsal region, in which I firmly applied the bandage to the chest, and obtained such support that the little fellow continued active in his sports. However, after a few months had passed, symptoms of spondylitis in the dorso-lumbar region developed, a boss appeared, and later paralysis. I always believed that if the first support had included the whole spine the lower projection would never have appeared.

If one wishes to thoroughly immobilize a diseased joint, it were best to fix the contiguous joints as well; so in inflammation of the vertebræ, the fixation should include as much of the spinal column as possible, at least the parts adjacent to the disease. In my case referred to, the thoracic vertebræ were made firm, while the lumbar were unduly movable; so that traumatism readily occurred at the junction of the two in the dorso-lumbar region, just as the bent fishing-rod breaks at the ferrule, or the axe or hammer handle breaks where the wood enters the steel.

So, in Pott's disease I am not using the short "cuirasse," and I use the long plaster jacket only occasionally. Both of these splints are intended as portable appliances. I have come to believe that we get better results and less deformity in the treatment of this disease by recumbency, combined with immobilization, and possibly traction, than in allowing the patient to be up and about with the superincumbent weight pressing upon the diseased bones.

Respectfully,

A. J. Steele.

COMMON-SENSE SURGERY VS. "ANTISEPTIC SURGERY."

To the Editor of The Medical News,

Sir: There has been so much written on the subject of antiseptic surgery, that it is only with a word of apology that the present communication is added to the list.

Old methods of operating, with dirty instruments and surroundings, were bad. After a time surgeons found out that, generally speaking, dirt and primary union were incompatible, and that dirty hands and instruments meant pus. They reformed, and, as is the rule in reformations, went too far—were not satisfied with simple cleanliness, but must needs have hyper-cleanliness. Lately they have come to see that it is not absolutely necessary to numb one's fingers with carbolic acid or to drench (often poison) one's patient with bichlorid in order to obtain a good and successful result. I am told that latterly such has been the drift of opinion, though, unfortunately, I have been rather out of the track of civilization, and where but little current medical literature was obtainable, and if ground already gone over is trenched upon, let this be my excuse.

The causative reason for this paper is the faint hope that perhaps a word, the result of practical experience, may be of some trifling value. It is not intended to be a scientific dissertation on the subject from a theoretic standpoint.

I left this country to practise in Honduras at a time when the prominent surgeons who were not carried away with the idea of (if the word may be used) hyper-antisepsis were the few and far exceptions, and I, for a time, went with the crowd, conscientiously numbing my fingers and cauterizing my hands in wild efforts to be antiseptic, and to get the patient into a similar much-to-be-longed-for condition. No matter what precautions

were taken, no matter how much washing and scrubbing were done, results were not always satisfactory. I finally concluded that I would discard carbolic acid and mercuric chlorid, and see what results were obtainable under a régime of simple cleanliness of instruments, hands, dressings, and patient, so far as soap and water would go. Instruments before being used were cleansed with 95 per cent. alcohol. In Honduras the field for experiment is practically unlimited and material very plenty. The results were most gratifying, and certainly no worse than formerly, to say the least. A series of as nearly as possible parallel cases was determined upon and carried out, in the course of which one hundred wounds of all sorts, from a simple scalp-wound to an amputation of the thigh or abdominal section, were treated. In fifty water only was used and in fifty all possible "antiseptic" rules were followed, including cleaning and boiling the instruments and soaking them in 5 per cent. carbolic acid solution, cleansing hands and wounds with 1:2000 bichlorid, and, in cases of abdominal section, washing the abdomen with 1:10,000 bichlorid solutions. These comparative results were decisive. In almost every instance the plain, clean-water treatment was followed by the most satisfactory result, and the reason did not seem to be difficult to find in the cases in which the wounds were closed and union between two raw surfaces was desired.

To my mind it is clear that an "antiseptic solution" of sufficient strength to do any good at all on the lines claimed for it as a germ-destroyer, must be strong enough to quite effectually kill the superficial layers of cells on the surfaces to be approximated, so that when they are brought together for union there is not the simple placing in contact of two raw surfaces, consisting of live cells, as is the case when harmless water is used, but between the living tissues of the flaps is a layer—or, rather two layers—of destroyed cells, which must be absorbed before the healthy tissues on each side can be joined by the new scar-tissue. Germs there will be, but they do no harm, as has been conclusively shown over and over again, unless they are of a virulent septic variety, and then they have been introduced upon the hands or unclean instruments of the operator.

In considering open wounds, when the result desired is a healing by granulation, the condition is just the reverse, and I have found swabbing out with carbolic acid solution (50 per cent.) to be an exceedingly valuable procedure. It is painful, to be sure, but what do we get? All germs are emphatically destroyed, not only on the surface, but for an appreciable depth below, and, in addition, there is left a thick covering of destroyed tissue, under which granulation may commence and get a healthy start before the covering has sloughed away.

In the treatment of uncomplicated gunshot wounds, "flesh wounds"—wounds of the soft parts only and not involving any large artery or vein—this 50 per cent. carbolic solution is extremely useful. The wound is thoroughly cleansed and the surfaces agglutinated. The cauterized tissue does not slough, except near the extremities of the canal, but is absorbed, and healing ensues with less discomfort and less pus than when the strong carbolic is not used. The method I have employed is very simple. An eyelet-probe, long enough to pass through and leave the eyelets projecting, is introduced and threaded with a narrow strip of gauze or unbleached muslin, the ravellings having been carefully removed. This cloth is saturated with the strong carbolic and drawn through the wound. In long gunshot wounds (say, six or eight inches), when tardy healing and much sloughing result, the cause is often found in a relaxed, sluggish condition of the tissues, which, when a proper stimulant is applied in the form of strong carbolic, is overcome.

Respectfully, PHILIP MILLS JONES, M.D.,
BROOKLYN, N. Y. Ex-Surgeon-General, Army of Honduras, C.A.

STENO, STENSEN, STENSON, STENON, OR STENONIS?

To the Editor of THE MEDICAL NEWS,

SIR: The trend of modern medical literature seems to be in the directlon of a multiplication of names for certain processes, operations, etc.—a fact to be deplored, as tending to confuse the student. My attention was called to this subject the other day by a question in anatomic nomenclature. I was taught to call the duct of the parotid gland "Steno's duct," my understanding being that it was so named on account of having been discovered by the Danish anatomist, Nicolas Steno (1638–87). Upon the use of this term the question was asked whether it should be "Steno's" or "Stenon's" duct.

Turning to the latest edition of Gray's *Anatomy* I find that the organ is there named "Stenson's duct," and the American editor adds that it is "more commonly, but less correctly, called "Steno's." In looking up other authorities I find opinion to be divided, although a majority uses "Steno." Billings' *Dictionary* says "Steno" is used in error for "Stenson," while the *Index-Catalogue of the Library of the Surgeon-General's Office* gives "Stenon [or Stenonis] (Nicolaus) or Stensen (Niels) [1636–86]," and a little lower down comes the title "Stenon's duct." Is there any way of telling which is the proper name of the organ?

Respectfully, DANIEL W. NEAD.
PHILADELPHIA.

To our inquiry the learned Librarian of the Surgeon-General's office, Dr. John S. Billings, U. S. A., has kindly replied: "The man's real name was Niels Stensen, but he Latinized this into Nicolaus Stenonis, and in one work into Stenonius. By his contemporaries he is usually referred to as Stenon. I do not think that the lack of uniformity is anything very serious; but if there must be uniformity, the name should be either Stensen, Stenon, or Stenonis. Steno has no good authority for it whatever, and he never signed his name in that way."

[This would seem to settle the disputed spelling, and plainly indicates that STENSEN is the correct form. It were certainly better to have uniformity, and though not alarmingly "serious," the question is of moment at least in cataloguing, indexing, etc.—EDITOR OF THE NEWS.]

M. W. Vignal, D.Sc., a distinguished French scientist, has died. He was one of the collaborators of M. Malassez, and had made valuable studies in histology, fermentation, and tuberculosis.

BEE-VIRUS FOR ACUTE RHEUMATISM.

To the Editor of THE MEDICAL NEWS,

SIR: The following extract appears in the *Bulletin* of the Division of Entomology of the Department of Agriculture (vol. v, No. 5):

"Mr. John Worthington, United States Consul at Malta, has sent us a clipping from the *Malta Standard* of April 11th, which states that the theory that the virus of the bee-sting is an infallible remedy for acute rheumatism has received most unquestionable confirmation from the practices of the country people in Malta. Bees are said to be plentiful on the island, and the virtue of the sting as a cure for rheumatism has been long established. It is, in fact, said to have been a common practice for generations past to resort to this remedy in all severe cases, the results being most favorable."

If the foregoing statement proves to be true, and the same virtue dwells in the virus of the sting of the surprisingly active bee of our country, will not some of our brethren who dwell in the rural districts give it a practical test and supply the cities with the article!

Very truly yours,

JAMES WOOD, M. D.

BROOKLYN, N. Y.

SOCIETY PROCEEDINGS.

FIRST PAN-AMERICAN MEDICAL CONGRESS,

Held at Washington, D. C., September 5, 6, 7, 8.

GENERAL SESSION.

FIRST DAY—SEPTEMBER 5TH.

THE RIGHT REVEREND WM. PARET, D.D., Bishop of Maryland, offered prayer.

The President of the United States, GROVER CLEVELAND, officially opened the Congress. He said:

"The part assigned me on this occasion admits of but few words. It, however, affords me the opportunity to say how pleased I am to be in any way related to an assemblage such as this, called together in furtherance of the highest and noblest purposes and designs. I hope I may also be permitted to add that the protection of the public health and the prevention of contagious diseases are objects properly brought under consideration at the capital of a nation which appreciates fully the serious importance of everything which aids in making intercourse between civilized countries and commerce between them safe and easy. It is also fitting that those who devote themselves to saving human life and the alleviation of human suffering should consider the modes of reaching these beneficent ends at the seat of a government whose greatest regard is the welfare and happiness of the individual citizen. It only remains for me to declare this Congress of the Pan-American Medical Society open for the transaction of the business which has called it together."

HON. JOHN W. ROSS, President of the Board of Commissioners of the District of Columbia, delivered an address of welcome. He said:

"The District of Columbia has entertained many distinguished public gatherings, but it has never known such a one as that which I now have the honor, in the name of the local municipality, to welcome to the national capital.

"For the first time in the history of the new world there are assembled in one of its capitals representatives of one of the oldest and most honored of the learned professions from all of the Americas.

"It is fitting that in the District which derived its name from that of the great discoverer, and that in the year set apart as the one in which the nations may do honor to his memory, the governments whose existence was hastened by the results of his genius and daring should send their representatives to a Pan-American convention.

"It is in keeping also with the spirit of the age which has prompted this gathering of representative men that the delegates so convened should meet not for individual or national aggrandizement, but for the loftier purpose of extending the range of medical knowledge, and for the alleviation of human suffering throughout the world.

"To a profession as progressive as that of medicine and surgery the results of such a conference cannot be over-estimated.

"When we consider the vast area of the surface of the globe here represented, the infinite variety of racial characteristics, of climatic conditions, and of all environments affecting health and disease, we can understand that such interchange of observation and experience was never before made possible.

"What may not be accomplished by all of the forceful men from all the governments here represented, by plans for the establishment and for the enforcement of international quarantine regulations, and for international coöperation against the spread of infectious and contagious disease?

"The municipal authorities in many of the cities of the United States are now endeavoring to locate hospitals for the treatment of contagious diseases near enough to the centers of population to avoid the dangers incident to a long transportation of patients affected with such diseases, and near enough to be within the range of a water-supply and of adequate sewerage facilities.

"It is the common experience of all who are charged with such responsibility that the dread occasioned to those who reside in the vicinity of the proposed locations assumes almost the proportions of a panic.

"If the position maintained by many eminent physicians be correct, that such hospitals if properly conducted are not likely to be the means of communicating disease to those residing near them, the public mind should be relieved of its needless apprehension, and if this great body of experts should deem the matter worthy of its consideration there can be no doubt that an authoritative expression of its views would do more than could be hoped for from any other source to educate the public mind upon this subject."

DR. WILLIAM PEPPER, the President of the Congress, then delivered an informal address upon the purposes of the Congress. The program, he said, exemplified the peculiar constitution of this body. The invitation extended by the United States had been cordially accepted by every country. As a part of the proceedings of each general session representatives of different countries would be called upon. This Congress represented the medical profession of the western hemisphere. This Congress, it

was hoped, was but the first of a series of congresses that would consider questions of such great moment to every country. They called this congress Pan-American, according to recent usage. Why not American? Are they not all Americans? He would be happy to see, as the result of a few such congresses, this Pan-American Congress merged into the American Medical Association, whence it had its origin.

DR. JOHN C. PHILIPPO, President of the Legislative Council of Jamaica, who was present as a delegate, made a brief address.

HON. J. B. MCCREARY, of Kentucky, made some remarks, in the course of which he pledged his aid in securing desirable medical legislation.

DR. F. MONTIZAMBERT, of Quebec, next spoke briefly as the representative of British North America. He urged coöperation on the part of the nations in sanitary works and in guarding against the spread of disease.

DR. JUAN J. ULLOA spoke as the representative of Costa Rica.

DR. J. N. HIBBARD, of Indiana, President-elect of the American Medical Association, made a short address and extended a cordial invitation of attendance at the next meeting of the Association, to be held in San Francisco in June next.

DR. CHARLES A. L. REED, of Cincinnati, the Secretary-General of the Congress, made an informal report upon the work of organization.

DR. S. S. ADAMS, the Chairman of the Local Committee of Arrangements, briefly recounted the work that had been done in preparing for the Congress, and spoke of their indebtedness to Senator Gorman for having secured action from Congress granting an appropriation for the entertainment of the Congress. He then explained in detail the arrangements made for the entertainment of the Congress and the arrangements for the meetings. In concluding, he expressed words of welcome in behalf of the members of the medical profession in Washington.

PROFESSOR FRANCISCO A. RIZQUEZ, of Caracas, Venezuela, delivered an address upon "The Relation of the American Flora to the Practice of Medicine."

SECOND DAY—SEPTEMBER 6TH.

DR. AUGUSTE COMEAU, of Haiti, delivered an address in French; DR. MENDIZABEL, of Orizaba, Mexico, spoke in Spanish.

DR. MANUEL A. MUNEZ, Surgeon-General of the Army of Peru, and DR. PEDRO LAGLEYZE, of the Argentine Republic, both spoke in Spanish.

DR. PLUMMER, of San Francisco, Chairman of the Local Committee on Arrangements for the next meeting of the American Medical Association, pointed out the advantages and attractions of his city and State for the projected gathering.

The formal address of the occasion was then delivered by PROF. RAFAEL LAVISTA, M.D., of the City of Mexico, the leading surgeon of that country, on "The Surgical Treatment of Cases of Gangrene."

PRESIDENT PEPPER announced that he had been requested to present a resolution, for reference to the International Executive Committee, as follows:

"In view of the importance of taking the necessary steps to insure the prosecution of the great continental work of the Congress, the International Executive Committee is hereby empowered and requested to appoint suitable international committees on the subjects of proper Governmental recognition of State preventive medicine, on uniformity in American pharmacology, and on medical education."

The following resolution was referred to the International Executive Committee, to be referred by it to the proper sub-committee for action:

Whereas, in the language of a British journalist, "greater energy and more systematic administration are much needed in regard to the sanitation of India, and England's imperial responsibilities in this matter are very heavy;"

Whereas the question has been asked in Austria, Russia, and France, "You English have, by your sanitary improvements, prevented cholera from gaining a foothold in England, why do you not attack it in its birthplace and prevent it from spreading into life in India?"

Whereas this question has been asked in America: "Why should the whole civilized world be allowed to suffer through the constant dread of invasion or invasion itself of cholera on account of the religious fanaticism of the Mohammedans of the East?" Therefore, be it

Resolved, That we respectfully recommend to her Imperial Majesty's Secretary for India these recommendations:

1. An imperial sanitary department attached to the Government of India.

2. A provincial sanitary department attached to each of the provincial Governments.

3. A local sanitary department.

Resolved, That the Secretary-General of this Congress be directed to furnish a copy of this to her Imperial Majesty's Ambassador at Washington, to be forwarded to Lord Kimberley, her Majesty's Secretary for India.

The following resolution was reported from the Section on Hygiene, indorsed by the Section on Railway Surgery, for the action of the whole Congress:

Resolved, That in the opinion of the Section of Hygiene, Climatology, and Demography of the Pan-American Medical Congress, the interests of the public health in every country should be and must be entrusted to a Department of the Government especially charged with their administration, and that while the precise form of administration may be left to legislation, the indispensable requisites are that it shall be national, that it shall have parity of voice and influence in the national councils, that it shall have independent executive authority under the limitations common to other Departments, and that it shall be intrusted to educated and experienced medical men, who alone are competent to assume its responsibities.

The resolution was referred to the International Executive Committee.

In the afternoon the delegates and their families were formally received by President Cleveland.

In the evening DR. WILLIAM PEPPER, the President of the Congress, delivered an address, in the course of which, among other things, he pointed out that "this Congress represents much more than our common interest in medical science and the common feeling of brotherhood which animates the entire profession. It is—indeed, it always has been, and forever may it so continue—the glory of

the medical profession that their allegiance is one and undivided, for their service is solely in the cause of truth and humanity. Dynasties have risen and crumbled; the map of the world has been changed times almost without number; but the march of medical science through the ages has been ever onward and upward toward those lofty goals—the prevention of disease, the relief of suffering, the improvement of the race.

"The history of European medicine for more than three hundred years is a record of which we may well be proud, when the enormous obstacles to progress are held in view. But it is sad to reflect on what has been done as contrasted with what might have been. The dense ignorance of rulers and masses on scientific questions, the slow progress of sound, useful education among the people, the huge claims of imperialism and of militarism, the wanton waste of luxury, have retarded research, have left but paltry sums available for the diffusion of knowledge, have hindered the embodiment in legislation and in actuality of much that would help the healing of the nations. It is an odd commentary on the vaunted civilization of to-day to contrast the sums doled out by the most enlightened Governments of Europe for the promotion of higher education and original research or for the suppression of preventable diseases, with those lavished on the vast hosts of armed men and the huge fleets of unwieldy armored ships deemed necessary for the maintenance of peace and order.

"Among the results which may be anticipated from this meeting is, I trust, the adoption of some well-considered plan for systematic conjoint study of our American remedies and their pharmaceutical preparations, looking to their scientific classification, to greater uniformity in their preparation, and ultimately to a single pharmacopeia for the entire continent.

"Everyone knows now how superfluous it is to say a word in defence of American literature, and certainly we who know how powerfully the opinions and practice of medical men in Europe and throughout the world are influenced by American writings may view our position with some complacency. Yet a survey of what America is actually contributing to medical literature shows clearly how far we are behind the nations which lead in medical thought.

"The apparently extraordinary number of medical journals in America is due chiefly to a substantial reason, and one which influences equally the existence of very numerous medical schools and medical societies. The vast extent of territory and the relatively sparse population render it impossible to serve the country with as low an average of medical men, schools, societies, or journals as is possible in more densely-populated countries. As to other and less satisfactory reasons which have operated, especially in the United States, to produce a great growth of ill-equipped medical schools and of poorly-supported medical journals it is not necessary to speak here. Indeed, the rapid rise in the standard of scientific requirements, both of medical men and medical literature, and the increasing appreciation on all sides of the fact that the higher medical education is the true interest both of the profession and of the public is accomplishing the much-needed work of checking the ill-considered establishment of new medical enterprises and of stimulating those in existence to more earnest life and more lofty aims.

"So true is this in regard to our medical journals in particular, that no one who has occasion to consult regularly the files of any number of them can fail to have been struck forcibly with the steady and decided improvement in the tone of their management and in the scientific quality of their contents.

"This Congress meets at a period of peculiar and critical interest in medical education, and I am glad to say that for the first time in the medical history of the United States we may feel proud to have such a meeting convened here, and to invite a close examination of our educational standards and facilities. I should fail in courtesy and in candor alike were I not to acknowledge the great value of the example which has been so consistently set by Latin-America and by Canada in the maintenance of a high standard of qualifications for medical practitioners.

"Fifteen years ago the medical profession of the United States arraigned severely the management of their overnumerous medical schools.[1] While Canada then exacted a reasonably strict entrance examination and a course of medical study extending over four years, with one session of six months in each year, and while every country in Latin-America exacted a collegiate degree or a rigid entrance examination, and a course of medical study extending over six years, it was the general custom with the medical schools of the United States to grant a diploma conveying the full right to practise medicine to applicants who had been admitted without preliminary examination, and had attended without term examinations two courses of lectures covering about five months, and had passed a single and final examination conducted by their own teachers, whose emoluments were derived solely from the fees of such students. This discreditable prostitution of a great educational trust had been gradually brought about by large causes upon which I may not now comment. But it is with justifiable pride that we may point to the admirable and sweeping reforms that have since been instituted. It remains true that the laws of many of the States allow charters for medical schools to be secured without any guarantee of the standard of education that shall be maintained. But the awakened sentiment of the profession and of the community has in a rapidly-increasing number of the States insisted that medical graduates before being admitted to practice shall pass a State examination conducted by an impartial board of examiners appointed by the Governor. The medical schools, to their honor be it proclaimed, have, with few exceptions, been foremost in the struggle to secure this wise and beneficent legislation. They have done much more. In advance of these laws which will insure a far higher standard of medical qualifications in the States fortunate enough to be so protected, the faculties of a number of the leading schools have forced their standard up at first to three years of obligatory study, and now to four years of eight months' study each, with a carefully-graded curriculum and with strict examinations before entrance, at the close of each term, and finally before graduation.

[1] Regular schools, 65; Homeopathic, 11; Eclectic, 4; total, 80 in 1877.

"When we recall that this has been done without the slightest governmental aid, and, further, that owing to the prevalent view that medical schools have been sources of large profit to their faculties the streams of private benefaction had not yet been directed in their favor, you will appreciate the high sense of duty and the devotion to science which have led these faculties to assume greatly increased labors with an expectation of considerably diminished remuneration owing to reduced attendance of students and to augmented expenditures.

"The Committee of Arrangements of this Congress has wisely provided for a tour of inspection of some of these institutions. It is trusted that all of our foreign delegates, and as many as possible of the members of this Congress, will avail themselves of this opportunity to examine the equipment of some of our leading medical schools. They will be gratified to find, in hospitals, in laboratories, and in libraries and museums alike, facilities which bear comparison with those of Europe. They will find an arrangement of studies, and, above all, an organization for the conduct of daily thorough bedside instruction in all branches of medicine, which leave little to be desired. It is easy to foresee, as another of the desirable results of such meetings as this held successively in various parts of America, such increased acquaintance with and confidence in our respective methods of medical education and medical treatment as will retain on our continent many of our students and many of our invalids who have been in the habit of going further to fare no better.

"A broad field opens before us for the study, with the aid of collective investigation, of the distribution and course of phthisis and rheumatism and other important diseases as influenced by race and locality. The endemic fevers, other than malarial and typhoid and yellow fever, which are said to prevail in various parts of North and South America, have long demanded systematic investigation to complete the study which the illustrious Drake began. We shall now have the opportunity of studying, equally by means of collective investigation, the relative effects of various climates on the numerous races now represented in America, and of determining more accurately the scientific and practical questions connected with our extensive series of health resorts, which embrace the finest examples of every type.

"Everyone now knows, or ought to know, that the most dreadful diseases are inseparably connected with definite organisms, that these organisms have special laws of development and distribution, that to destroy or exclude them is to avoid the disease, and that to tolerate conditions which favor their development is to encourage and invite the attack of the disease. When these simple, demonstrable propositions are considered in connection with such scourges as cholera and yellow fever, and typhus and typhoid fever, and scarlatina and diphtheria, and epidemic meningitis, it needs no further argument to prove the value and the necessity of quarantine, and of efficient medical inspection and protection. Nor does it need further argument to show the wisdom of establishing laboratories of hygiene at many points over the country, of equipping them amply with the ablest men and the finest apparatus, and of endowing them liberally, so that the search after the yet unknown causes of disease, and after the best methods to prevent the development of such causes as are known, may be prosecuted with ceaseless vigor.

"There should be, and the day cannot be far distant when there shall be, in the cabinet of every Government here represented a secretary of public health, of rank, influence, and prerogative equal to that of any other cabinet officer.

"Here, then, is the last and greatest service to be rendered to science and to the nation by our Congress. Our combined influence will be irresistible when used in advocacy of higher education; in carrying out large plans for the scientific study of our national life, as affected by social and climatic influences; in the adoption of remedies and remedial measures of demonstrated merit, and in the insistence upon a fuller recognition of the lofty function of preventive medicine. 'Salus sanitasque Reipublicæ, suprema lex.' Let us acquire here a closer touch with each other, a deeper faith in our profession and its noble destiny, and a stronger determination to labor in brotherly coöperation for the loftiest ideals of service to science and the race."

(To be continued.)

NEWS ITEMS.

An Army Medical Board will be in session at Washington City, D. C., during October, 1893, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before September 15, 1893, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-two and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which, his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing Dr. George M. Sternberg, Surgeon-General U. S. Army, Washington, D. C.

The Journal of Surgery, Gynecology, and Obstetrics is a new publication emanating from Atlanta, Ga. Dr. C. Evans Johnson is the editor, and he is supported by a strong list of collaborators. The first number bears the date of July, and contains a number of original articles, some well illustrated, besides reports of the proceedings of societies and departments for abstracts in surgery, genito-urinary and venereal diseases, gynecology, and obstetrics.

Cholera.—The progress of cholera continues, with but little abatement. During the week new cases have been reported from Holland, Austria, Hungary, Germany, Italy, Russia, and Belgium. The disease has also appeared in England at Grimsby, a Lincolnshire seaport, and at Hull. Numerous deaths have occurred. A fatal case has occurred in this country, in Jersey City, but no others have come under observation.

HAIG'S URIC ACID THEORY.[1]

BY HENRY SEWALL, PH.D., M.D.,
OF DENVER, COL.;
PROFESSOR OF PHYSIOLOGY, MEDICAL DEPARTMENT UNIVERSITY OF DENVER; VISITING PHYSICIAN TO ST. LUKE'S, ST. ANTHONY'S, AND ARAPAHOE COUNTY HOSPITALS.

IT may be taken as an axiom in medical philosophy that no therapeutic formulary is satisfactory, complete, or scientific which is not supported by a knowledge of the physiology and pathology of the processes that it is designed to modify, as well as of the bio-chemic effects of the remedial agents employed. In medicine, however, as in other inductive sciences, generalizations are made from the association of individual facts; and as here the number of accurately observed facts is wholly inadequate to the purpose, it is not surprising that in daily practice we apply, as inductions from ill-founded generalizations, therapeutic agencies that act in a manner we hardly know how on pathologic conditions we do not understand in the least.

The "practical man," falsely so called, is satisfied with getting results; the scientific physician rests not until the results are explained. The diagnosis and rational treatment of "organic" disease is a comparatively simple matter, for we have a tolerably fair though rough knowledge of the general functions of single organs and of the action on them of various agencies; but the diagnosis and rational treatment of "functional" diseases is a very different matter, for these imply an estimation of the normal, physical, and chemic changes in every living part of the body; they imply a consideration of the mutual relations of the living mechanisms, and also of those lines of misdirection that the working machine may take, turning what we call physiologic processes into what we indefinitely call pathologic ones. Indeed, the very term "functional" disease in pathology, like the expression "catalytic action" in chemistry, is perhaps itself merely the insignia of our ignorance.

It may be doubted if there is any manifestation of energy in the body that is not the outcome of organic change. For instance, Hodge[2] has found that electric stimulation of the nerves entering the posterior spinal roots in kittens produces in the root-ganglia marked morphologic changes, easily recognized under the microscope, which disappear when the animal is allowed to rest a sufficient time after stimulation. Hodge has also discovered the interesting fact that in sparrows similar ganglionic alterations are found as a result of the ordinary fatigue of a day's activity. The evident conclusion is that even so evanescent and feeble a manifestation of energy as a nerve-impulse produces in the nerve-center an organic change that is none the less important because unrecognizable.

It is a significant observation of Musser's[1] that while in text-books of medicine small space is given to the consideration of functional as compared with organic diseases, in actual practice the former class of disorders, taken in a large sense, includes about four-fifths of the cases that come under care. It will be admitted on all hands that the truth in medicine will endure; that the false and unessential must gradually be sifted from it. We can only know as truth that which has been logically proved. When a writer treats in the same paragraph and in the same way facts that are proved and beliefs whose probability seems to him of such weight that he accepts them as proved facts, he not only displays a lack of scientific training and unfitness as a teacher, but he also throws actual obscurity on the subject that he attempts to illumine. Moreover, the assumption that the results of medical treatment prove the truth of the hypothesis under which the treatment was instituted is an error that is often as serious in its effects as it is common in practice. Clinical observation and therapeutic facts must go hand-in-hand; but in our present ignorance of physiology and pathology the results of treatment predicate no explanation of bodily changes.

There is a subject of the medicine of to-day that by its importance in pathology, by the frequency of the disorder and its far-reaching effects, has won deserved attention. It is the subject of lithemia, uric-acidemia, or what not, all names for it implying a morbid condition of which uric acid is the constant factor, if not the cause. The symptomatology of lithemia is about as complex for a physiologic disorder as is that of hysteria in mental disease. The pathology of the disease is the outcome of processes

[1] A paper read before the Arapahoe County Medical Society, June 13, 1893.

[2] Amer. Journal of Psychology, 1891, and Journal of Morphology, 1892.

[1] Address, Forty-second Session Medical Society of Pennsylvania.

of which we know almost nothing. The analogy of such chemic knowledge of physiologic reactions as we possess would indicate that the physiologic chemistry of lithemia is of appalling complexity.

There is no field in medicine in which it is more difficult to separate facts from beliefs than here. The unbiased investigator knows that in treading such an unknown wilderness as the living body any theory not supported on all sides by proved facts is practically certain to be erroneous.

It therefore seems not only excusable but desirable for us now and then, like a man lost in the woods, to stop and consider whether we are working on true lines—to number and weigh the facts supporting our theory—no matter how satisfactory this may appear to be.

It is hard to estimate the debt that medicine owes to Alexander Haig, if only for the energy and perseverance that have made him the latest prophet of lithemia. Already his work has had considerable influence among physicians, and everyone who reads his fascinating pages must feel a strong inclination to accept his sweeping generalizations, which ascribe to uric acid human disorders of every complexion—from gout to diabetes, and from the simple feeling of discontent to a suicidal melancholia.

The book published by Haig was the outcome of nine years' research, chiefly on the cause and treatment of headache, from which he was a periodic sufferer. In general, he found that on a meat-diet his headaches were intensified, while on non-nitrogenous food they diminished or disappeared. Further study led him to the conception of the close relationship of migraine to gout, and he conceived the idea that uric acid was the cause of the former, as of the latter. He accordingly began to estimate the uric acid eliminated from his own person, and found a constant difference between the proportion excreted during the period of headache and that passed before and after the attack. By easy reasoning he connected the concomitant symptoms of the headache, the slow pulse of high tension, the mental depression, the disinclination for exertion of mind or body, the cold surface and extremities, with the character of the urine and the amount of uric acid contained in it. He says, p. (3): "I soon found that in altering the uric acid I could alter the symptoms related to it; that when I produced an increased excretion with an alkali I produced the headache, mental depression, cold surface, slow pulse, and scanty urine, and that when I stopped the plus excretion with an acid I removed all these symptoms. . . . Then, I also noticed that in curing a headache by giving an acid to diminish the excretion of uric acid, I always produced a certain amount of pricking and shooting pain in my joints (generally in those which had been most used on the day in question), and it naturally occurred to me that the uric acid was held back in those joints and produced the pains. . . . Since then I have found not only that an attack of gout can be produced by giving acid, but what I had observed was only a single instance of a general law, and that all substances which increase the solubility of uric acid increase its excretion in the urine, and do good in those joint-troubles which are due to its irritating presence; while, conversely, all substances which diminish the solubility of uric acid diminish its excretion in the urine, and also increase those irritations in the joints and other fibrous structures which are due to its presence. On such comparatively simple facts and observations the whole of my writings have been based, and as side issues I have been led to reason on the pathology of epilepsy, in some cases of which I have found exactly similar fluctuations in the excretion of uric acid to those met with in migraine, thus explaining a clinical relationship between these two diseases which had long been known and written about; also on the pathology of rheumatism and rheumatoid disease, the causation of Bright's disease, Raynaud's disease, and paroxysmal hemoglobinuria and anemia."

If Haig's conclusions are correct, we have seen the practice of medicine placed at one bound, in some of its most important relations, upon a mathematic basis, and Haig deserves to be mentioned with Hippocrates and Harvey. I do not pretend to dispute the clinical statements made by Haig, or even assail the accuracy of his methods. Whether the exhibition of a certain remedy has caused such or such modification of certain symptoms is a matter in which we can only accept the assurance of the observer. It is notorious, however, that widened therapeutic experience almost invariably cripples the quickly-gained reputation of new remedies, or of old ones applied in a new way.

In a preceding paragraph it has been asserted that any theory concerning physiologic processes which is not supported throughout by established fact is almost certain to be wrong. In examining Haig's work we are appalled at the intrepidity with which conclusions are drawn from premises established in his own consciousness. We are astonished that in a nominally scientific publication the statements of other authors that are in favor of his theories are accounted reliable facts, while many views that have a contrary tendency are not mentioned at all. The work is of a kind in which medicine might well be richer as an essay on the suggestiveness of certain fundamental data, while, at the same time, it is an example of a kind of medical literature of which there is far too much; in which a few plain facts are

so interwoven with ingenious hypotheses that the unwary reader is scarcely able to winnow one from the other.

Haig's reasoning is chiefly based upon an unwarranted assumption, which he by no means succeeds in proving, namely, that the ratio of formation of urea to that of uric acid in the body is constant. The untold complexity of the chemistry of the tissues and of the floating pabulum of the body has for him no difficulty, because he ignores it. The ratio of formation of urea to that of uric acid he estimates as thirty-three to one, though it may be said in passing that Salkowski and Leube put the ratio at fifty or sixty to one, and Landois at forty-five to one. This constant proportion in production being assumed, any variation from it in the urea and uric acid excreted must mean that that substance which is deficient in the urine is retained somewhere in the body.

Again, it is assumed that the urea is never retained in excess in the body, but that its excretion takes place *pari passu* with its formation. Therefore, according to Haig, as the ratio of excretion of uric acid to that of urea is demonstrably variable, the amount of uric acid within the body varies, and is at any time either above or below a certain mean quantity. This excess of uric acid may exist either in the blood or in the tissues. In the tissues the uric acid may either lie latent, not producing symptoms, as in the spleen; or, in certain situations, it may give rise to well-marked disturbances, as in the gout of joints. It is to the uric acid dissolved in the circulating blood that Haig ascribes most of the evils in his category. The proportion of uric acid in the tissues and in the blood is assumed, without proof, to depend on the relative alkalinity or acidity of the media, the precipitation of uric acid occurring in situations where the reaction is least alkaline, and where, it is assumed, it can be least readily held in solution.

Attention may here be called to the careful work of Sir William Roberts,[1] who concludes on experimental grounds that the uric acid of the circulation exists in the peculiar form of a quadriurate, having quite distinctive reactions and solubilities. He also adduces strong reasons for believing that it is the presence of an excess of salines, and not of an excess of acids, that determines the precipitation of urates, and for this reason the favorite location of tophi is in the joints. Again, though it is generally admitted by physiologists that the kidney-substance is peculiar in having an acid reaction, Landois[2] says that "the heart, liver, and kidney are rarely affected by deposits of uric acid." Absolutely no proof is offered by Haig of his therapeutic assumption that the exhibition of acids clears the blood of uric acid by causing its deposition in the tissues, while the exhibition of alkalies causes the resolution of this precipitate and loads the blood with uric acid. Haig assumes, after only a cursory and altogether insufficient attempt at proof, that excess of uric acid in the blood determines an increased arterial blood-pressure by causing contraction of the peripheral bloodvessels. All the evidence of value that we have on this subject goes to show that vascular tension, so far as it depends on the chemistry of the blood, varies with the alkalinity of the fluid only. Any statement that it depends on the uric-acid contents is purely gratuitous.

Haig pays but little attention to the results of Roy and Sherrington,[1] who found that in the dog injection of alkalies into the circulation was immediately followed by a diminution in the volume of the brain—that is, produced vascular contraction—while the injection of an acid caused an increase of volume—vascular dilatation. In view of the fact that in the dog's economy very little uric acid is produced, and that, moreover, the effects are stated by Roy and Sherrington to immediately follow the injection, it certainly seems probable that the change in brain-volume is due to a direct action of the acid or alkali, and not to the diffusion of a hypothetic uric acid to or from the tissues.

Haig makes no reference to the well-nigh classic work of Gaskell,[2] who showed that the isolated frog's heart fed by a nutrient fluid containing one part in 20,000 of alkali has its tonicity increased, and may gradually come to rest in the phase of systole; the opposite effect and rest in diastole being produced by transfusion with minute doses of lactic acid.

It is easy to see the meaning and to grant the truth of the observation made by Sir Wm. Roberts,[3] that the "arthritic incidents of gout may be said, not improperly, to be simply incidents pertaining to the precipitation of these crystals (sodium biurate) in the structures of the joints."

The *tissues* are the seat of bodily life, and their elements form the origin and destination of nerve-supply; and Haig runs counter to well-founded physiologic doctrine when he declares that in general uric acid is inert when deposited in the tissues, but provokes its manifold symptoms only when present in the circulating blood. In the light of modern physiology, the only conceivable way in which uric acid retained within the blood could give rise to symptoms, that is, effect the tissues, is indirectly by influencing the caliber of the blood-vessels and so modifying arterial pressure; but Haig takes the trouble to point out that alteration

[1] Brit. Med. Journ, 1892.

[1] Journal of Physiology, vol. xi, p. 85.
[2] Journal of Physiology.
[3] Loc. cit.

of blood-pressure, *per se*, does not cause the symptoms in question, but that the presence of an excess of uric acid is a necessary feature (p. 117).

Haig lays great stress on the clinical observation, valuable in itself, that the amout of urinary water excreted varies inversely as the amount of uric acid contained in it. He considers this fact as the natural effect of an excess of uric acid in the blood, causing general constriction of the arterioles and consequent diminution of blood flow to the kidney. In support of this statement he inappropriately cites some experiments of Lauder Brunton, who caused in animals an increase of vascular tension and diminution in the flow of urine as the result of the injection into the circulation of certain drugs. It is well to mention that Roy,[1] when, by an ingenious apparatus, he directly measured the changes of volume in the living kidney, found that the curve representing the kidney-volume ran parallel with the curve of general arterial pressure—in other words, that the blood-supply of the kidney varied directly with arterial blood-pressure. He found, also, that expansion of the kidney was accompanied by an increased, and contraction by a decreased, flow of urine. Landois, quoting Heidenhain, states the remarkable fact that great changes in the caliber of the renal artery, experimentally produced, failed to alter greatly the amount of blood flowing to the kidney; he concludes in consequence, that the blood-supply of the kidney is proportional to the arterial pressure. Indeed, Haig himself finds it convenient to ascribe the excess of urinary water in certain forms of nephritis to high arterial tension. Haig makes use of the fact that in fevers the blood is less alkaline in reaction than in health, and assumes the uric acid produced during fever to be thrown down in the tissues, being afterward re-dissolved, causing the uric-acidemia of convalescence. He does not refer to the statement of Salkowski and Leube[2] that, in general, in fevers the excretion of uric acid is increased (pp. 102, 336, 461).

Haig makes the statement that bodily exertion and activity of the skin diminish the alkalinity of the blood and cause precipitation of its uric acid in the tissues. We would naturally expect as a consequence that among working-men—who, moreover, at least in America, eat a large proportion of meat in their diet—gout would be a frequent disease; this is notoriously not the case.

It would be interesting to weigh the evidence for Haig's confident assertion (p. 12) that uric acid is formed in the kidney. Much force is attributed by Haig to the announcement of Roberts that in the hours of the forenoon the blood is more intensely alkaline than at other periods of the day. Haig draws the conclusion that, during this "alkaline tide," the blood is surcharged with uric acid that had been stored up in the tissues. If this belief were correct, we would expect to find the morning hours to be normally marked by those subjective feelings of depression and ill-being that Haig so well describes; but against this view we have the universal verdict of healthy mankind.

The criticism that applies to Haig's work, the unscientific confusion of facts and beliefs, is abundantly characteristic of most other writing on this subject. Haig is simply the most notable example of the false method. One cannot but wish that the spirit of Darwin were more common in medical writings. His patient search for evidence against his assumptions, his careful separation of fact from belief, would alone make his work an admirable addition to the medical school curriculum.

In the pathology of the uric-acid diathesis, Haig's main mistake has been in assuming that the ratio of production of urea and that of uric acid remain constant under all conditions. We know next to nothing of the physiologic chemic changes leading to the production of urea and uric acid in the body; we only feel sure in an obscure way that oxygen plays an important part in them. We know that the absorption of oxygen is a variable matter; and there is reason to think that oxygen, after entering the body, can be diverted from one use to another, according to the kind of food ingested, and possibly, also, under drug-action. That uric acid is a less oxidized compound than urea we know, because uric acid by oxidation may give rise to urea; but the most respectable physiologic opinion points to the conclusion that in the body urea is not the normal descendant of uric acid, but that the two bodies are the resultants of different chains of events. In fact, it has been plausibly suggested that the formation of uric acid in our bodies is a remnant of ancestral processes that were once extremely important, but now chiefly of historic and pathologic interest; as, for example, the vermiform cecal appendix appears to be in an anatomic sense.

It is the teaching of physiology that the nitrogenous excreta have two different sources of formation in the body. One is the so-called circulating proteid, which is variable in amount and feeds, but forms no part of, the living tissues, and the other is the living tissues themselves. It seems highly probable that the pathology of the circulating proteid represents a different set of conditions than that of the tissue proteid. We know that proteid in the food is chemically changed in the alimentary canal, giving rise to a long series of compounds of different character; and these, again, are produced in variable ratios, depending on the nature of the

[1] Journal of Physiology.
[2] Die Lehre von Harn.

food and the activity of the digestive organs. Of the complexity of these digestive changes anyone will be convinced who will read the work of Kühne and Chittenden on the chemistry of digestion. As to the further history of these products after their absorption into the body, we can only speculate.

It may be accepted as a physiologic fact that every kind of food-matter—proteid, carbo-hydrate, or fat—besides having its own intrinsic food-value by reason of the chemic potential energy locked up in it, also exerts on the organism a sort of drug-action by which it modifies the vital processes of protoplasm. This statement is a deduction from a long array of physiologic observations that it would be tedious to survey, but it is manifestly an important consideration in practical dietetics.

We can imagine two ways in which diseases not due to the introduction of morbid agents into the body may have their origin, both due to certain physiologic errors of working: 1st. Errors of formation, by which is meant that the chemic changes of the healthy body either do not occur with normal intensity, or that they proceed along lines of disintegration somewhat different from those that are usual, and result in the formation of chemicals that are poisonous to protoplasm; it seems highly probable that oxygen plays the most important rôle in this altered metabolism. 2d. There are errors of elimination in which, owing to sluggishness of blood and lymph circulation, retardation of the diffusion-currents through the tissue-elements, waste products, poisonous when in excess, are heaped up in, and interfere with the function of, living matter.

It has been generally held that uric acid is the responsible factor in producing the disturbances represented under the title of lithemia. Attention has already been called to the conservative observation of Roberts, according to which the influence of uric acid in gouty joints has simply mechanical significance. However convenient a clinical sign excess or deficiency of uric acid in the urine may be, it is at present utterly fallacious to accept uric acid as the cause of physiologic disturbance. We estimate the vitiation of respired air by the percentage of carbon dioxid contained in it; yet it is well known that air which has been breathed does not acquire its peculiarly noxious qualities from the carbon dioxid in it, but from an as yet unknown, organic constituent occurring in trifling amount. So in the uric-acid question, it is quite possible that the dangerous products are the results of changes of which the formation or accumulation of uric acid in the body is only a concomitant and not an essential factor.

My endeavor has been not to obscure this question, but only to make plain, if possible, some of the difficulties to be overcome and the futility of leaning too heavily on theories supported by data of which we know next to nothing. This is an almost untrodden field for physiologic and pathologic experiment, and herein must the problem receive its final solution, which can only be reached through the directing thoughts that must arise from long-continued and exact clinical observation.

HYSTERICAL APHONIA.

By W. SCHEPPEGRELL, A.M., M.D.,
ASSISTANT SURGEON TO EYE, EAR, NOSE AND THROAT HOSPITAL, NEW ORLEANS, LA.

This not uncommon manifestation of hysteria is characterized by an inability of the adductor muscles of the larynx to place the vocal bands in position for phonation. Unlike true paralysis of the adductors, however, there is present a functional and not an organic pathologic condition of the nerves controlling the muscles of adduction.

In phonation, the arytenoid cartilages, to which the vocal bands are attached, are approximated and rotated inward and the glottis is reduced to a narrow slit. In paralysis of the adductors, or in the hysteria which similates this form of paralysis, this narrowing of the glottis does not take place, hence the loss of voice.

Hysterical aphonia, like other forms of hysteria, is found chiefly in young women of a neurotic temperament, and cases are very rarely presented in which other manifestations of hysteria are not observed. The voice is lost, but the patient is able to communicate in a whisper. If the larynx be examined with the laryngoscope, it will be observed that, during attempted phonation, the vocal bands approximate, but not sufficiently for vocalization.

As the name implies, there is in this affection simply a loss of voice, characterized by an entire absence of any inflammatory process or of any organic condition as a cause of the aphonia. It should not, on the other hand, be considered a mere counterfeit on the part of the patient, to excite sympathy; this is very rarely the case.

Hysterical aphonia comes on suddenly, and is sometimes paroxysmal in character, as in other forms of hysteria. Sometimes it is occasioned by fright. The diagnosis of this condition is not difficult if the laryngoscope be used and all of the features of the case are carefully examined. Before concluding that we have before us a case of hysterical aphonia, we must carefully exclude other conditions in which aphonia may be present as a symptom. These are bilateral paralysis of the adductor muscles, bilateral paralysis of the recurrent laryngeal nerve, the presence of a foreign body or tumor, or cicatricial adhesions mechanically interfering with the movements of the vocal bands, some forms of acute and chronic laryngitis, and destruction of the vocal bands.

By means of the laryngoscope the presence of a foreign body, a new-growth, or extensive ulceration of the vocal bands, may be ascertained without difficulty, and acute and chronic laryngitis of sufficient intensity to cause aphonia may be recognized by the conformation and color of the bands and of the adjacent parts.

Bilateral paralysis of the adductors is an exceedingly rare affection, the only cases, five in number, having been reported by Mackenzie, and the diagnosis of these cases is not beyond question. Bilateral paralysis of the recurrent laryngeal nerve is also very rare. In both of these affections, if the laryngoscope is used, the vocal bands will be found widely separated, assuming the "cadaveric" position.

Although there is usually more mobility of the vocal bands in hysterical aphonia than in these two affections, still the differentiation between them by means of the laryngoscope alone would not always be easy. In the attempts at vocalization, however, we find a marked difference. In hysterical aphonia the whisper is natural, but in bilateral paralysis of the adductors, and in bilateral paralysis of the recurrent laryngeal nerve, the whisper is labored, with marked phonatory waste, due to the inability of the patient to approximate the vocal bands. Cough is frequently present in hysterical aphonia, but is never found in true paralysis, as this act necessitates the approximation of the bands. In a doubtful case the administration of chloroform will clear the diagnosis, as the first stage of the anesthesia will bring out the voice, unless true paralysis exists.

The prognosis in cases of hysterical aphonia is good, especially in recent cases. In long-standing cases certain atrophic changes may take place in the muscles, as a result of disuse, but even these cases yield to careful treatment.

The treatment should be both constitutional and local. Constitutionally, arsenic, strychnin, iron, valerian, or the bromids, should be used according to the indications of the case. The influence of ovarian or uterine disease should not be overlooked. The local treatment depends upon whether the case is acute or chronic. In recent cases I have had excellent results from using the faradic current applied externally to the neck. The patient, having been assured that the treatment will absolutely restore the voice, is directed to count from one to ten while the current is passed through the neck, the electrodes being applied on each side of the larynx. Each time that the patient counts, which she will do in a whisper, the current is increased in intensity, the patient being urged, at the same time, to use all her efforts to raise her voice. After a few attempts the voice usually "breaks," and a sound above the whisper is heard. If it be deemed advisable, the treatment may be continued on the following day, although in many cases the voice may be restored in one sitting. If more than one sitting is required, the applications should be carefully continued until some improvement is observed over that of the preceding visit. In chronic cases the treatment is essentially the same, except that the improvement is usually much slower. In these cases, in addition to the faradic applications, the galvanic current should also be used, on account of its tonic effects upon the muscles which have been weakened from disuse. The negative electrode should be applied within the larynx, and the positive electrode externally over the larynx.

CASE I.—Mrs. F., a lady of thirty-two years, had become frightened by the fall of her child. She had fainted, and when she recovered consciousness could speak only in a whisper. I sent for my portable faradic battery, and applied the current in the manner described, with the result of a complete and permanent restoration of the voice.

This case is mentioned only as an example of the acute cases. They are quite frequently met with.

CASE II.—Miss Ella J., forty-one years of age, had suffered from aphonia for eighteen years. After having shown other manifestations of hysteria for about one year, she suddenly lost her voice, being able to speak only in a whisper. After having been treated for some months without success, she was told that change of climate was necessary. She remained away for six months without any change in her condition. On her return treatment was again commenced, but discontinued after three months, the patient being still able to speak only in a whisper. She spent six months of each year at various summer resorts. During the eighteen years of her aphonia she had yielded at different times to the solicitations of her friends, and had consulted a number of physicians without, however, recovering her voice. After the age of thirty-two the patient rarely exhibited other manifestations of hysteria.

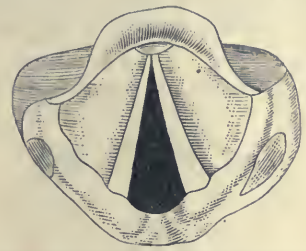
When I first saw this patient my impression was that the case was an illustration of those rare cases of bilateral paralysis of the adductor muscles of the larynx, or of bilateral paralysis of the recurrent laryngeal nerve, but a careful examination enabled me to exclude these diagnoses.

A physical examination of the chest gave negative results as to the presence of an aneurism or enlarged glands. The quiet and natural sound of the whisper was very unlike the labored whisper of true paralysis, and there was no phonatory waste. A laryngoscopic examination showed the mucous membrane of the larynx to be somewhat anemic, but I could find no evidence of any pathologic condition. There was a certain degree of mobility of the vocal bands, but they could not be approximated sufficiently for phonation. (Fig. 1.)

After examination I stated to the patient and her sister that I did not consider the disease incurable, but that it would require persistent treatment for at least three months. As they agreed to submit to the trial the following plan of treatment was car-

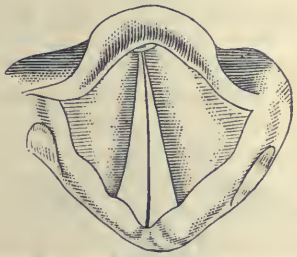
ried out: Every morning an internal laryngeal electrode was introduced into the larynx, and a galvanic current of one milliampère passed through the parts, the positive electrode being applied externally over the larynx. At first this was practised for only a few seconds at a time, but later the patient was able to tolerate it for several minutes. Every afternoon the faradic current was applied externally, the patient counting from one to ten during each application.

FIG. 1.



Functional paralysis of the adductors. Laryngeal image during phonation.

FIG. 2.



Normal laryngeal image during phonation.

For twenty-three days the applications were made mornings and evenings without any perceptible improvement in the voice. On the twenty-fourth day, however, the patient phonated for the first time, the sound being made as she repeated "eight, nine, ten." In spite of my efforts it was seven days before she again uttered these numbers aloud. After this I succeeded in obtaining a sound every two or three days until the forty-fourth day, after which no day passed in which the patient did not count some of the numbers aloud. My efforts were now directed to increasing the numbers which she could pronounce, and on the fifty-first day the patient for the first time counted from one to ten aloud. The voice was at first weak and wavering, but soon increased in strength, and the patient also occasionally spoke a few words aloud at home.

After the sixtieth day the visits were reduced to once daily, the galvanic current being applied first and the faradic current immediately afterward. She now counted without difficulty, and spoke frequently at home, but complained that she would "get out of breath" while speaking. This symptom gradually disappeared, and on the eighty-fourth day the patient was discharged, cured.

CASE III.—This is perhaps one of the most unique cases of hysteria of the larynx on record. The only similar case which I find recorded is one reported by Mechede[1] as bilateral paralysis of the abductors of the larynx. In this the dyspnea was so great that preparations were made to perform tracheotomy to prevent suffocation, when the patient suddenly recovered from her condition. In my own case, however, the dyspnea was so great that tracheotomy was actually performed, and not rashly, but after a deliberate consultation of four physicians.

On December 9, 1892, I was called by my friend, Dr. W. E. Brickell, to see a case of dyspnea in which asphyxiation seemed to be imminent. The patient was a young lady, twenty-two years of age, and a candidate for sisterhood in a convent. When seen the symptoms were not quite so alarming as they had been the preceding night, but still the dyspnea was very great, and the loud stridulous inspirations could be heard at a considerable distance, while the patient gasped with every breath. The voice had disappeared and the patient spoke in short, jerky whispers. The temperature was normal and the pulse 98°. Examination of the neck showed a cicatrix resulting from a former tracheotomy.

The following was the interesting history of the case given me by Sister C., a lady of unusual intelligence, who had attended the patient during her previous illness:

Miss G. had an attack of influenza in January, 1892, while at Milwaukee. She was confined to bed for five days, after which she resumed her duties as usual. In February she had a second attack, and a few days later lost her voice, being unable to speak, except in a whisper. Various remedies were administered without, however, restoring her voice. On March 24th a throat-specialist was called in, who, evidently surmising the hysterical nature of the affection, made an application of electricity to her throat and stated that she would soon recover her voice. I was unable to ascertain the manner in which the electricity had been applied, but presume that it must have been an external application of the galvanic or faradic current. At 10 o'clock of the same night alarming symptoms of dyspnea began to develop; the breathing became gasping, and the stridulous inspirations could be heard at a considerable distance. The nearest physician was hastily summoned, and he pronounced the trouble hysteria and ordered potassium bromid. As the symptoms became more distressing the physician whom she had consulted during the day was sent for, and he found the condition of the patient so alarming that he at once called for a consultation. At this consultation there were present four physicians, who pronounced the case as one of paralysis of [the abductors of (?)] the larynx. The condition had now become so grave that asphyxiation seemed imminent, and preparations were at once made to perform tracheotomy. On account of the condition of the patient it was considered dangerous to administer chloroform or ether, and the operation was performed without the use of an anesthetic. In spite of this, however, the patient appeared as

[1] Berliner klin. Wochenschr., 1878, No. 17.

insensible to the pain as if the operation were being done upon a cadaver. A tracheotomy-tube having been inserted the breathing became easier. The air of the room was kept moist and at a temperature of about 80° F. There was a slight elevation of temperature following the operation. The patient's respirations, however, were so weak that she could not expel the mucus which accumulated in the tracheotomy-tube, and this had to be kept constantly clear with a feather to prevent symptoms of suffocation.

The tube was left in position for twelve days. On its removal the breathing was unimpeded, but there was still aphonia, the voice not returning until five days later. Ten weeks later there was another but milder attack of dyspnea, which subsided in three days under the administration of pil. sumbul comp.

Miss G. was now sent to her parents, where her health improved, and there were no further symptoms of aphonia or dyspnea. Her urgent solicitations to return to the convent were acceded to, and in September she was sent to the convent at Chattowa, La., where she took charge of a small school. Ten weeks afterward she again lost her voice, which returned under the use of the compound sumbul pills.

In November difficulty in breathing again developed, and the patient was hastily sent to the convent at New Orleans for treatment. Dr. Brickell, the attending physician of the convent, was sent for, who prescribed quinin valerianate every four hours. The following day, the symptoms being still distressing, strontium bromid was ordered.

Desiring to demonstrate the hysterical nature of the attack, Dr. Brickell administered chloroform. During the first stage of the anesthesia the appearance of the patient became so alarming that the administration of the chloroform had to be discontinued, and every effort directed to prevent the asphyxiation that appeared imminent. The last rites of the Church were administered.

Early the following morning Dr. Brickell called me in consultation.

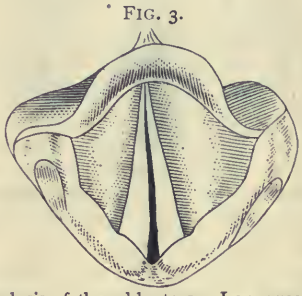
I had the patient placed in a chair and made a careful laryngoscopic examination. The first glance showed the cause of the dyspnea. With each inspiration the vocal bands, instead of separating, and leaving the triangular opening of the glottis, were drawn together, and gave rise to the stridulous inspiratory sound.

The alarming appearance of the patient, the duration of the attack, and the fact that tracheotomy had been performed on the patient during a similar attack, suggested that the case before me was one of true paralysis of the abductor muscles of the larynx, but a more careful examination, with a consideration of all of the features of the case, enabled me to exclude this diagnosis.

In the first place, all of the milder attacks were evidently of hysterical origin. We had also to consider the fact that, although the vocal bands were in apposition, as required for vocalization, aphonia existed, and, in true paralysis of the abductors the voice is altered, *but there is no aphonia*. The present attack occurred during the catamenial period, and the former violent attack had likewise taken place during a similar period. The laryngoscopic image (Fig. 3) also was not characteristic of true paralysis. Instead of the vocal bands, on inspiration, remaining lifeless or making feeble attempts to increase the glottic space, they were really drawn together with each inspiratory effort, resembling more a spasm of the adductors.

I therefore made a diagnosis of functional paralysis of the abductor muscles of the larynx. In view, however, of the serious termination of the previous attack, and as, moreover, the patient's condition appeared very dangerous, and more alarming symptoms of asphyxiation might appear again at any time, I advised that the patient be sent to the Eye, Ear, Nose, and Throat Hospital, so that, should I be wrong in my diagnosis, and the case really demanded it, tracheotomy could be performed without delay.

FIG. 3.



Functional paralysis of the adductors. Laryngeal image during inspiration.

FIG. 4.

Normal laryngeal image during inspiration.

My advice was followed, and the patient was at once conveyed to the hospital. Here Dr. H. W. de Roaldes, surgeon-in-charge, saw the patient with me, and agreed with my diagnosis.

Strychnin sulfate and dilute phosphoric acid were administered three times daily. Electricity, according to the method of central galvanization, was applied twice daily. Sulfonal was given at night, under the influence of which the patient slept, and, *during this time, the breathing became quiet*, the stridulous breathing, however, returning as soon as the patient awoke.

Under this treatment the dyspnea disappeared on the fourth day, and the laryngoscopic examination showed the normal movements of the vocal bands. Aphonia, however, still existed, for which I used the method of external faradization of the neck, as described. The third application was followed by

complete restoration of the voice, and the patient was sent back to the convent.

I informed the mother superior of the convent that, in my opinion, Miss G.'s health was not adapted to the restrictions and duties of the sisterhood, and advised that she should be permanently sent back to her parents. This was according done, and the young lady's health has since then been excellent.

136 GRAVIER STREET.

THE RESULTS IN NINETY CASES OF PULMONARY TUBERCULOSIS TREATED AT THE WINYAH SANITARIUM AT ASHEVILLE, N. C., FROM MAY 1, 1891, TO MAY 1, 1892, WITH A COMPARISON OF RESULTS OBTAINED WITH AND WITHOUT THE USE OF TUBERCULIN.

BY KARL VON RUCK, M.D.,
ASHEVILLE, N. C.

IN a paper presented to the American Medical Association, May 7, 1891, I reported my first series of 25 cases treated with tuberculin during the winter of 1890 and 1891. Of cases in the early stage, which I designated as Class A, I had 5, of which 3 were reported as apparently recovered, 1 as greatly improved, and 1 as improved.

Of cases in the middle stage, which I designated as Class B, there were 7 treated. Of these, 4 apparently recovered, 2 improved greatly, and 1 improved.

Of the cases in the third stage, designated Class C, there were 13 treated; of these, 4 were greatly improved, 6 were improved, 1 was slightly improved, and 2 were not improved.

During April of this year, two years later, a careful inquiry was made by correspondence with the patients, their friends or their physicians, as to their present condition, the object being to learn the permanency of the results obtained and the outcome of the cases after a period of two years.

The results of this inquiry were presented in a paper read before the American Climatological Association on May 26th, and were as follows:

The 5 cases belonging to Class A (early stage) have all recovered and report themselves perfectly well in every way.

Of the 7 cases belonging to Class B (middle stage), 6 have made a final recovery and reported themselves perfectly well, while 1 case relapsed, was treated again, and was again greatly improved.

Of the 13 cases belonging to Class C (advanced stage), 3 are still greatly improved, 3 others remain improved, and 7 have died. This gives, at the end of two years, among cases in the first stage, 100 per cent. of recoveries; among those in the second stage, 86 per cent. of recoveries and 14 per cent. with improvement; and in the last stage, 46 per cent. with improvement.

I desire now to report 36 additional cases treated with tuberculin between May 1, 1891, and May 1, 1892, and to show their condition at the time of their discharge, and also to give the results obtained in 54 other cases not treated with tuberculin, but otherwise managed and cared for exactly in the same way as were the 36 patients who received treatment with tuberculin additionally.

Before proceeding with these reports, permit me to state my general experience with tuberculin and my position as to the use of the remedy from the beginning to the present time.

When in Berlin in November, 1890, I protested there against the manner of employment of the remedy, especially against the use of doses that induced general symptoms, such as fever, severe aching, headache, nausea, loss of appetite, etc., and which were called a reaction; and immediately on my return to this country I warned the profession, in three or four short articles, against doses that were followed by such symptoms; and although I did not then know that the remedy would or could determine beneficial effects in doses that caused no such disturbances, I felt that the first consideration was to find a safe mode of administration.

My protests were, however, little heeded, and the sad experience with this remedy is common knowledge, especially in the advanced stage of the disease, to which its use was largely confined, because cases at an early stage held aloof after realizing that tuberculous patients did not all get well as was expected, and that deaths from pulmonary tuberculosis continued to occur as before.

The public press, which had raised false hopes among patients and their friends, reported cases of death, in which tuberculin had been given, in a manner which soon checked the enthusiasm. "Took Tuberculin and Died" was a frequent heading of such newspaper items. Those of the profession who had used the agent in large doses were necessarily disappointed, and those who looked on and watched became doubtful at first, and prejudiced next; so that, after the lapse of a few months, the patients themselves feared the remedy and would not have it administered except as a last resort; while the profession, with but few exceptions, absolutely condemned it as dangerous and useless, without even having given it a trial.

This stage was practically reached when I reported my first 25 cases.

Constant communication with the source of origin of the remedy, and the good results obtained by such men as Stricker, Langenbuch, Schmitt, Thorner, Schede, and others, assured me, however, that my results were, at least in a measure, due to the remedy; the more so, as, in my past experience, I had not seen as good and satisfactory improvement and

recoveries from other measures. At this pessimistic stage, disbelievers in the remedy attributed my reported results to climatic and general treatment and to the care and supervision of these patients while under treatment, and the prevalent prejudice forced me to restrict the use of the tuberculin to such patients as themselves requested it, and then only after obtaining the consent of the physician who had sent the patient to me.

Under such restriction the remedy was, from May 1, 1891, to May 1, 1892, further applied in 36 cases. During this period 54 patients were treated without it. The classification into stages is made as nearly alike as possible for both series of cases. In each case treated the sputum contained tubercle-bacilli.

REPORT OF 90 CASES OF PULMONARY TUBERCULOSIS

Treated at the Winyah Sanitarium, Asheville, N. C.
From May 1, 1891, to May 1, 1892.

36 cases treated with tuberculin:

Class.	Number treated.	Apparently recovered.	Per cent.	Greatly improved.	Per cent.	Improved.	Per cent.	Slightly improved.	Per cent.	Stationary.	Per cent.	Worse.	Per cent.
1st stage	6	5	83.3	1	18.7	...	...	...	...	...	...	...	...
2d "	15	8	53.4	6	40.0	1	6.3	...	...	...	...	...	...
3d "	15	...	...	7	46.6	5	33.3	2	13.3	1	6.3	...	...
Total	36	13	36.1	14	38.9	6	16.6	2	5.5	1	6.3	...	...

54 cases treated without tuberculin:

1st stage	6	2	33.3	3	50.0	1	16.6	...	...	...	...	...	...
2d "	14	2	14.1	6	42.8	5	35.7	1	7.0	...	...	...	...
3d "	34	...	...	3	8.8	12	35.3	11	31.3	4	11.1	4	11.1
Total	54	4	7.7	12	22.3	18	33.3	12	22.3	4	7.4	4	7.4

In Class A, I include all cases having one or both upper lobes involved, but without destructive changes and with the general health comparatively good. In class B, I include cases with circumscribed softening or cavitation, but still in fair physical condition. In Class C, the local disease was still further advanced, with more extensive breaking down and larger cavities, and with considerable constitutional impairment. If any doubt arose as to the proper classification, the patient's general condition determined the choice.

The average duration of the treatment was 152 days in cases treated with tuberculin, whereas it was 178 days in cases that did not receive tuberculin. Cases treated for less than a month are excluded from both classes, as are also such as arrived in such a condition that the case was absolutely hopeless.

Cases reported as apparently cured were free from all subjective symptoms; there was entire cessation of cough and expectoration, and the last specimen of sputum examined did not show the presence of tubercle-bacilli. In other words, there was apparently an entire restoration to health. Locally, beyond the evidences of more or less retraction of the affected portions of lung, there was no other evidence of the tuberculous process.

As greatly improved, I report all cases in which the tuberculous process seemed to be arrested and in which the subjective symptoms subsided to a degree that but slight morning cough or expectoration remained, the patient regaining his general health. I have no doubt that ultimately some of these cases will completely recover. This could probably have been brought about by further treatment; but such patients are, as a rule, unwilling to remain longer and are satisfied to take their chances for the future, so long as they feel perfectly well.

The terms "improved" and "slightly improved" are relative and depend upon a comparison between the conditions found on admission and those shown at the last examination. All patients reported as improved showed a gain in weight and strength. Of those treated with tuberculin (with the exception of one in Class C, reported stationary, who had made a gain of 3 pounds and lost it again), all gained in weight. The greatest gain was 31 pounds, the least gain, 2 pounds, with an average, for the first stage of 9 pounds; for the second stage, of 13½ pounds; and for the third stage, of 5¾ pounds. Of the patients treated without tuberculin, 39 gained in weight between 1½ and 26 pounds; in 8 others there was but a slight gain; in 9 cases there was a loss. The average gain in weight in cases in the first stage was 10¼ pounds; in cases in the second stage, 6 pounds; and in cases in the third stage, only 3½ pounds.

Comparing now the results, we have 6 cases in the early stage in each series, but we find that, with the addition of tuberculin to the treatment, 5 patients have apparently recovered and one has been greatly improved, while, without the remedy, there were only 2 recoveries, with 3 cases greatly improved and 1 improved. Still I consider the results practically the same, for I have no doubt that, by a continuance of the treatment in the cases that did not receive tuberculin, three greatly improved cases would eventually have recovered. There is, however, this difference, that the average duration of residence in the Sanitarium of the patients in the early stage receiving tuberculin was 133 days, whereas it was 184 days in those that did not receive tuberculin, and a completion of the treatment in the greatly improved cases would increase the difference still more. In the second stage, Class B, the utility of tuberculin appears

much greater and a greater saving in time is also manifest.

There were 53 per cent. of recoveries under tuberculin against 14 per cent. without it, and the difference in the improved cases is also equally manifest.

The average residence in the institution of the patients taking tuberculin was 138 days, as against 189 days for patients that did not receive it.

No real recovery resulted in either series of cases in the third stage. Under tuberculin there were, however, 46 per cent. at this stage greatly improved, while without the remedy there were only 9 per cent. greatly improved, and 35 per cent. improved, showing more than twice as good results from the use of tuberculin.

The average duration of treatment in the third stage in the institution under tuberculin is greater than for those who did not receive it; but this is owing to the fact that, on account of the less satisfactory progress of patients that did not receive the remedy, some of them became discouraged and returned home, whilst the patients having tuberculin were highly pleased and satisfied, and therefore remained longer.

From the evidence accumulated during two and one-half years' use of the remedy, and from the results obtained in my first series of 25 cases and those of the 36 cases reported in this paper, I believe myself justified in claiming that tuberculin has been a great aid in my work, and having seen no unfavorable effect whatever from its administration upon the plan described by me,[1] I believe myself justified in recommending its use, not only in the earlier but in all stages of pulmonary tuberculosis, when no contra-indication exists.

As the chief contra-indication to treatment with tuberculin, I consider the existence of septic infection, and the fever due to it, which, unless controlled by other means, necessarily leads to exhaustion of the patient. Tuberculin has no power over such processes, nor over many other complications that may arise in the course of chronic pulmonary tuberculosis, and no effects must be expected from it except in the purely tuberculous affection that has not advanced to the stage of breaking down.

From private information recently received it appears that Dr. Koch has by no means abandoned his endeavors for the improvement of this specific remedy for tuberculosis, and a substance is now being tested in the Institute for Infectious Diseases, in Berlin, which is eventually to supersede the present tuberculin. This is not given by inhalation, as reported in the journals, but is administered subcutaneously in the same way as tuberculin is now given, but it will not be presented to the profession until its advantage over the present tuberculin is clearly established in the clinical department of the Institute.

I have seen no advantage in Hunter's modification, and its use requires the same circumspection as does the original remedy, while it seems less constant in its composition and effect.

Neither was there any important advantage derived from the modification of Klebs, and I have come to the conclusion that if tuberculin is to be used at all, the original remedy, with which we have now the greatest experience, both as to its dangers and benefits, is the preparation to be employed.

[1] See Therapeutic Gazette, June, 1893.

CLINICAL MEMORANDUM.

REMOVAL OF THE GASSERIAN GANGLION.

BY CLAYTON PARKHILL, M.D.,
OF DENVER, COL.;
PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN THE UNIVERSITY OF COLORADO; VISITING SURGEON TO THE ARAPAHOE COUNTY, ST. LUKE'S, DEACONESS' HOME, AND ST. ANTHONY'S HOSPITALS, ETC.

THIS history of a case of excision of the Gasserian ganglion was, at the time of operation, the first of its kind in Colorado. There were but three cases on record in America and five in Europe. The patient was referred to me at the Arapahoe County Hospital from the service of Dr. Eskridge, and the following history is clipped from his case-book:

Mary E. H., aged sixty, a native of Ireland and married, has been in the United States since her eighth year. She has lived in Colorado seventeen years. The family history is unimportant, except that there is a record of rheumatism on the father's side. The health in childhood was good and remained so until her twenty-eighth year, three years after her marriage, when she began to suffer from rheumatism. This affected the joints, especially the distal ones of the fingers. All these joints of the right hand are distorted by local deposits, except the thumb, but none of the other joints of this hand is affected. The distal joints of the index, middle, and ring fingers of the left hand show deposits. The larger joints of the extremities have occasionally been the seat of pain, but none of them except the left ankle is enlarged. From her thirty-eighth year to her fifty-second, she suffered considerably with these rheumatic pains. Eight years ago the first division of the fifth nerve on the left side began to be the seat of great pain. Soon afterward the second division became involved, and three years ago the third division. Eight years ago the second division of the nerve was excised at its exit from the infraorbital foramen. This gave relief for about five months. A second operation was then performed, in which all three divisions were excised at their exit from their respective foramina. This gave relief for about five months. A third operation was performed six months after the second. This was similar in character to the others, but confined to the second division, and gave no relief whatever. After this operation she began to take

morphin for the relief of pain. The dose was gradually increased until about one year ago, when she was taking 120 grains per week. She continued to take this amount on an average until her admission to the hospital. When the pain was unusually severe she would frequently consume from 60 to 120 grains in twenty-four hours. The drug was always taken by the mouth. During the last year she has inhaled chloroform from a bottle almost constantly while she was awake. In the ten days preceding the operation she had consumed four pounds of the anesthetic. At times it was impossible to obtain more than a few hours' sleep in the night. Since her admission to the hospital she has been made tolerably comfortable by taking from twelve to fifteen grains of morphin each day hypodermatically. In addition to this she has continued to take chloroform. Her nutrition is fairly good; the urine is free from albumin and sugar. Her face has an expression of suffering and is exquisitely sensitive to touch on the left side. There are no areas of complete anesthesia, although the left side of the nose and places on the left side of the face are partially anesthetic. The exacerbations of pain seem to have their beginning in the inferior division of the nerve. There is no paresis or paralysis of the muscles of the face. Hearing is fair and equal on both sides. The temperature, prior to the operation, ranged between normal and 101½°; the pulse between 101° and 128°.

On September 3, 1892, which was the day previous to the operation, she was given a brisk cathartic of Epsom salts and was carefully bathed. The left side of the head was shaved, and this area of the scalp, together with the entire left side of the face, was scrubbed with soap and water, afterward with sulphuric ether, and finally with a solution of mercuric chlorid (1:1000). Towels, sterilized in 1:2000 solution of mercuric chlorid, were then placed over the field of operation and confined there by bandages. On the following morning, the day of operation, a rectal injection was administered. Immediately preceding the operation the patient was given an ounce of whiskey with one-thirtieth of a grain of strychnin. Chloroform was used as the anesthetic. When the patient was under its influence, the cleansing process of the preceding day was again employed. The method of operation was practically that of Rose. The incision began just external to the outer canthus of the eye, and was carried backward along the line of the zygoma to a point immediately in front of the ear, thence downward to the angle of the jaw, thence forward along the line of the jaw so far as the facial vessels. This incision was deep enough to sever the skin and superficial fascia. The flap included by these lines was dissected up and turned forward. A dental engine was used to perforate the zygoma at either end for subsequent suture. Considerable embarrassment and delay were caused by the failure of this instrument to work properly. The bone was sawed between the drill-holes and turned down, together with the masseter muscle. It was found that the opening was somewhat small, owing to the unusual width of the zygoma anteriorly, and it was enlarged with bone-cutting forceps. The coronoid process was not drilled, but severed from the jaw, together with the insertion of the temporal muscle, and drawn upward. This exposed the pterygoid fossa. The internal maxillary artery was ligated in two places and cut between. Great difficulty was experienced on account of lack of light in the depths of the wound, until Dr. Jesse Hawes suggested the use of a mirror to reflect the sun's rays. This proved quite satisfactory, and the origin of the external pterygoid muscle was now peeled off from its attachment to the greater wing of the sphenoid. The foramen ovale was located, and a half-inch trephine was applied anteriorly and external to it. On the removal of the button, the intervening bridge of bone between the trephine-opening and the foramen was cut away with chisel and mallet. The interior maxillary division of the nerve was now followed into the skull. It was impossible to see the Gasserian ganglion, but passing a small curet along the nerve to the location which the ganglion should occupy, it was scraped away. The wound was flushed with sterilized water, and the parts brought again into their normal relations. Instead of reuniting the coronoid process to the jaw, it was cut away. The zygoma was not united to the bones, but simply sutured to the temporal fascia. I believe that this was the first time that this procedure has been made use of, and the result was so satisfactory that I shall hereafter pursue this method. The time saved in drilling the zygoma and introducing the sutures is very considerable, and if equally good results can be obtained by suture to the fascia, it will certainly tell in the patient's favor. The skin-wound was united by interrupted silk sutures. No drainage was used. Small pieces of protective were placed over the wound, over this a few layers of sterilized iodoform-gauze, and this covered by an abundant dressing of simple sterilized gauze, sterilized cotton, and a bandage.

The patient reacted well and her progress to recovery was uninterrupted. The pain was completely and permanently relieved. The temperature on the evening following the operation was 101.4°, the next morning 99.8°, and from that time it rapidly declined till the third day following the operation, when it was normal and afterward remained so. On the seventh day the wound was dressed and found perfectly healed. The morphin was gradually withdrawn until the fourteenth day, at which time she was taking half a grain per day. On this date she was discharged from the hospital. Up to the present time she has not experienced the slighest return of the pain. A period of ten months is not sufficiently long in which to estimate the permanency of the result obtained by this operation, but if the good following it is in proportion to the difficulty of the procedure, there can never be cause for complaint.

HOSPITAL NOTE.

CARCINOMA OF THE ESOPHAGUS.

German Hospital, Philadelphia.

SERVICE OF ADAM TRAU, M.D.

[Reported by DR. ALFRED HAND, JR., Resident Physician.]

L. S., a male, aged seventy-eight years, was admitted June 19, 1893, with a history of having been troubled for some months with a profuse muco-purulent expectoration, out of proportion to the accompanying slight cough

He mentioned some slight difficulty in swallowing, but this did not seem to be present after he entered the hospital. He complained of diarrhea, which was easily controlled, and of pain in the stomach and in the lumbar region. These pains were constant, but not violent.

There were rather large, moist râles at the left apex, and prolonged expiration at the right, so that the case was thought to be one of pulmonary tuberculosis in old age, especially as the temperature was very irregular; but no tubercle-bacilli were found in the sputum. The diet of milk, eggs, bread, broth, and cereals was swallowed without difficulty.

The patient emaciated rapidly, and died about two weeks after admission.

At the post-mortem examination, purulent bronchorrhea was found in both lungs, with a small, encapsulated, cheesy mass at the right apex. Each pleural cavity contained a large amount of fluid. There was a large, cauliflower-like carcinoma growing from the inner surface of the esophagus, in its middle third, directly back of the heart. (See annexed illustration.) The lumen of the esophagus was but slightly narrowed. The intoxication to which the growth gave rise was well shown by the spleen, which was enormously enlarged and almost fluid; and by the liver, which was soft and dark-red. The left kidney contained seven cysts, and the right three cysts. The pylorus was the seat of fibroid thickening.

The University of Colorado announces that on and after the 1st of September, 1895, attendance on four annual lecture courses of nine full months in length will be required of all candidates for graduation.

MEDICAL PROGRESS.

[*Multiple Calculi of the Bladder and Prostate Gland.*—Estes (*Lehigh Valley Medical Magazine*, vol. iv, No. 4, p. 137) has reported the case of a farmer, twenty-five years old, in which seven years previously, without appreciable cause, there appeared a urethral discharge, at first slight but subsequently profuse. The possibility of venereal infection was strenuously denied. Shortly afterward there was complaint of pain in the penis, about an inch behind the glans. The man continued at work for two years, but finally the symptoms became so pronounced that he was compelled to give up. There was no especial difficulty or pain in micturition until within a period of a few months. There had never been symptoms of renal calculus or pain referred to the bladder. Some five months before coming under observation, the man had had an attack of acute illness, attended with fever, burning pain, and swelling far back in the perineum about the lower part of the rectum, which was diagnosticated as acute prostatitis. The urgent symptoms were relieved by a fairly copious discharge of pus *per urethram*. From this time the man was confined for the most part to the house and for the last four weeks to bed. He was now emaciated, presenting an appearance of anxiety, suffering, and hectic. Micturition was unattended with pain; the quantity of urine voided was thought to be about the same as usual; it was passed more frequently than in health, though it could be retained for three or four hours without much difficulty. Examination with a searcher disclosed the presence of what seemed to be a large, rather soft, and immovable calculus. On rectal examination the prostate was found moderately enlarged and tender. The man was weak and his pulse was rapid and small; his appetite was impaired and he was daily having fever and sweats.

The condition seeming to be desperate, immediate operation was advised. Fourteen ounces of urine were withdrawn by means of the catheter. Examination showed the secretion to be turbid and to have a fetid odor; the reaction was alkaline and the specific gravity 1030. There was no response to tests for albumin and sugar. In the sediment that formed upon standing, phosfates and a little pus were found. A dose of calomel was given and followed by a saline. The bladder was washed out during twenty-four hours with a warm solution of boric acid. Upon careful examination of the bladder and prostate under anesthesia it was concluded that the large mass felt at the base of bladder on rectal examination was a stone, and the examination with the searcher showed that this was not only large, as well as soft externally, but also fixed. It was therefore decided to perform supra-pubic cystotomy. The peritoneum not reaching down upon the anterior surface of the bladder, the peritoneal cavity was inadvertently opened, a small amount of urine gaining entrance. A fold of peritoneum was at once caught and stitched to the margins of the incision; then the wall of the bladder was brought upward and joined to the abdominal wound by sutures; finally a puncture was made into the linea alba, and a stream of weak sterilized saline solution introduced into the peritoneal cavity through the nozzle of fountain-syringe. The incision into the bladder was

now enlarged, a finger introduced and a large encapsulated or encysted stone found. It proving impracticable after several attempts to retain it within the grasp of the forceps as it lay, after much care and difficulty the stone was separated from the walls of the bladder, turned, grasped, and removed. It was then found that there was evidently another pretty large stone at the bottom of the cavity occupied by the first, from which it was separated by a layer of soft tissue. This stone could not be extracted from above without lacerating what seemed to be the trigone of the bladder; so that a median perineal incision was made, and with a great deal of difficulty and much loss of blood a second stone was extracted. No other concretion could be felt. The patient being now almost exhausted by loss of blood, the lower cavity was packed with gauze, a fresh supply of hot saline fluid poured into the abdominal cavity, a glass drainage-tube introduced into the pelvis, as much fluid as would come out being permitted to escape from the abdominal cavity, a large rubber drainage-tube introduced into the bladder, and the patient hurried to bed. He required active stimulation for a time, but rallied well, and on the second day was doing nicely. Everything connected with the operation did well for a time, until the evening temperature became slightly elevated and the general condition began to fail somewhat. A little pus now began to appear in the perineal wound. Upon introducing a probe a hard mass was found near the neck of the bladder in a cavity of the prostate, and a small oval stone was removed by means of the dressing-forceps. Immediately about an ounce of pus escaped. On further examination two other stones were detected and removed in the same way. Thereafter the fever abated and the general condition improved. The perineal wound still continuing to discharge a little pus, after a week another examination was made and an additional stone found, and in a few days still another one was found and removed. Thereafter the man steadily improved, and he was finally dismissed, fifty days after his admission into the hospital. The aggregate weight of the seven stones was 1480 grains.

Neuritis of Infectious and Toxic Origin.—In illustration of the diversity of origin of peripheral neuritis, BARET (*Archives de Méd. et de Pharm. Milit.*, 1893, No. 7, p. 49) reports three interesting cases, in one of which the poison of enteric fever acted as the cause; in another, the syphilitic poisoning; and in the third, alcohol. The first occurred in a man, twenty-seven years old, in which upon recovery from an attack of enteric fever, complicated by myocarditis, great weakness was found to exist in the hands. Examination disclosed a condition of wasting, with impairment of tactile and thermal sensibility, with reaction of degeneration, extension of the proximal phalanges and contraction of the distal phalanges, and vaso-trophic changes in the peripheral distribution of the ulnar nerves. Decided amelioration followed upon tonic treatment and rest.

The second case occurred in a young man convalescent from erysipelas, who gave an antecedent history of syphilitic infection. The symptoms simulated those of anterior poliomyelitis. There were present weakness, slight wasting, numbness, and tingling in the lower extremities, with analgesia of the soles of the feet and enfeeblement of the patellar tendon-reflexes. Pressure upon the muscles gave rise to a disagreeable sensation, while pressure upon the nerve-trunks caused severe pain. The muscular sense was preserved. In the upper extremities weakness and wasting were less marked, while paresthesia and anesthesia were more pronounced. There was also slight convulsive tremor of the fingers. Micturition and defecation were not deranged and there were no cerebral or ocular complications. The administration of strychnin and sulfurous baths was followed by no improvement. The patellar reflexes became entirely abolished and the muscular sense in the lower extremities totally lost. Treatment with mercurial inunctions and potassium iodid was now instituted, but was suspended upon the development of a left pleural effusion, for the relief of which puncture was several times performed. The general condition became quite poor; the legs became edematous; and it was found that thrombi had formed in the femoral arteries. Antisyphilitic treatment was now resumed, and decided improvement was immediately noted in the local and general condition.

The third case occurred in a man, twenty-three years old, addicted to alcoholic excess, who presented symptoms suggestive of posterior spinal sclerosis. For a number of months it had been observed that fatigue was induced with undue readiness; the gait was awkward; lancinating pains appeared paroxysmally, particularly in the distribution of the sciatic nerves; at night there occurred cramps in the calves of the legs. There was, however, no girdle-sense and no visceral crises. Upon the left thigh and leg were circumscribed areas of analgesia, while upon the soles of the feet all forms of sensibility were impaired. The skin-reflexes were preserved. The patellar reflexes were exaggerated, but there was no ankle-clonus. There was a tendency to foot-drop. Gait and station were quite ataxic. Tremor was marked in the upper extremities. The shoulders and arms presented several disseminated areas of analgesia. Marked improvement supervened upon a milk-diet, withholding alcohol, and the administration of large doses of iodid.

Radical Operation for Unincarcerated Hernia.—LEUW (*Archiv für klinische Chirugie*, Bd. xlvi, H. 1, p. 40) analyzes the results of a radical operation upon 119 hernias of various kinds in 106 persons, performed by Professor Kocher at Berne, and concludes that if carried out with appropriate aseptic and antiseptic precautions, the radical operation is *per se* not a dangerous operation. If other therapeutic measures (trusses) fail to afford relief for an existing hernia, the radical operation is indicated in early childhood. While youthful age is an indication for the radical operation, advanced age does not of itself constitute a contra-indication. Constitutional disturbance or disease of other important organs would be a contra-indication. The success of the operation is dependent first, upon the method adopted; secondly, upon the aseptic course of the case; and finally, upon the degree of separation of the columns, the size and character of the hernia, and whether there be a single hernia or more than one. The result is in slight degree governed by the age of the individual, but is quite independent of the age of the hernia.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 Walnut Street,
Philadelphia.

Subscription Price, including Postage in North America.

Per Annum, in Advance . . . . . $4.00.
Single Copies . . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Philadelphia.

SATURDAY, SEPTEMBER 16, 1893.

TENOTOMOMANIA.

At the meeting of the Ophthalmic Section of the Pan-American Medical Congress there was, with a few exceptions, a manifest inclination toward a more conservative, that is to say, a truly medical treatment of heterophoria or insufficiencies of the ocular muscles. One entire day was devoted to the discussion of these problems, and the members were delighted at the evidences of carefulness and sanity manifested.

It seems to be largely admitted that, generally speaking, we are at present or have but lately been indulging in an exaggeration of the function and importance of the surgical aspect of medicine. "The glamor of successful surgery" has so bedazzled the eyes of the lay world that our own professional perspective is at least very faulty, and instead of preserving a sane sense of the proper proportions we have too thoughtlessly acquiesced in the popular craze of glorification of all men and things surgical. To be a good general physician certainly requires as great intellectual and professional ability as to be a great surgeon. Every conservative physician—nay, every frank surgeon—will admit that surgical gynecology has often and injuriously intruded itself into the proper domain of general medicine and that many unnecessary operations have been and are still daily being performed; and unnecessary surgery is medical crime. Strictly speaking surgery is not medicine, it is the despair and renunciation of medicine, a *dernier ressort*, as it were, and has place only when cure is beyond the means of the therapeutic art distinctly and properly bounded. When the physician, the healer and curer by physiological methods, can do no more, then arises the need of the surgeon. However glorious his office, however splendid his achievements, and however successful his results, we should never lose sight of the proper limits both of his field of work and of those of the general physician. Entirely too often we have thus lost sight and sense of these boundaries, and the surgeon has often arrogated to himself work that did not belong to him.

In ocular therapeutics, especially as regards imbalance of the extra-ocular muscles, there has been an outrageous excess of surgical impertinence, a genuine tenotomomania. We have flung conservatism and a healthy judicial attitude of mind to the dogs and have indulged in a kind of surgical debauch, with reckless disregard of physiology, the general condition of the patient, and of central and allied abnormality. Where else in the whole domain of surgery and medicine do we witness proceedings allied to those of tenotomy for heterophoria? No one will contend that these cases have the faintest resemblance to the contracted tendons and plainly morbid conditions existing in talipes. Where else do we operate on functionally paretic or incoördinated muscles?

Every ophthalmologist also knows, too well knows, of many cases wherein ocular tenotomies for insufficiency have not cured or where they have made matters worse. Everyone knows that the results of the healing after tenotomy are entirely doubtful, and often disappointing. Everyone knows that the operation to relieve one or two degrees of imbalance requires a superhuman delicacy and accuracy on the part of the operator. Pretence of possession of this accuracy is simply silly.

It is also fast coming to recognition that, owing to the very peculiar and complex interrelations and functions of the ocular muscles, as well as from a hundred other reasons, philosophic or experiential, these muscle-troubles, supposed, and so-called, are often not muscle-troubles at all; they are not always peripheral in origin or in essence, but are often of central origin. The malfunction resides in the innervation and the innervating

centers. For example, upon a patient with eighteen degrees of esophoria, complete tenotomies of both internal recti have produced temporary muscle-balance, but in ten days the eighteen degrees reappeared and the man stood just where he was before the operation.

In the first place many of these incoördinations are due to general disease, such as anemia, tabes, pelvic disorder, syphilis, etc., and require proper general treatment to reëstablish healthful normality of function. One of the speakers of the Congress detailed a number of cases that had come under his observation, in which operations on the muscles had been worse than useless because the paresis was plainly due to cord-disease.

Then, again, a large number of these incoördinations are due to the uncorrected ametropia. The tenotomist, despite himself and despite his remonstrance, ignores the fact or depreciates its importance, that the refractive error produces muscular defect, and the correction of the ametropia either relieves the reflex symptoms or cures the muscular imbalance. It is perfectly possible, nay, it is highly probable that hyperopia and hyperopic astigmatism may be the chief etiological factors in the production of *both* esophoria and exophoria. A single cause may produce diametrically opposite results, according to its strength and according to the circumstances and conditions among which it operates.

Finally, in a large balance of cases not due to general disease, or to ametropia, it is certain that gymnastic exercises may reëstablish the desired muscular equilibrium. All success by this method depends upon the kind of exercise, and how it is carried out. In the case of other paretic muscles (supposing, for argument's sake, that the muscles are primarily at fault) we do not cut them, but we endeavor to stimulate them to healthy action and development by gymnastics, by hygienic and physiologic measures. Why not also do the same with the muscles of the eye?

There is a proper place for tenotomy for insufficiency, but it should be resorted to only after the foregoing methods have been tried.

We congratulate the Ophthalmic Section of the Pan-American Medical Congress on the noteworthy success of its entire series of sessions, but especially upon the fact that there was started a healthy conservative reaction against the excesses of the over-enthusiastic tenotomist.

POPULAR INSTRUCTION IN THE PREVENTION OF TUBERCULOSIS.

THE response on the part of physicians as regards the distribution to tuberculous patients and their friends, of pamphlets to prevent the spread of the disease, has been unexpectedly gratifying. Several thousands of the pamphlets have already been ordered.

We have also received from The Pennsylvania Society for the Prevention of Tuberculosis copies of two pamphlets, issued by the Society and distributed gratuitously. The pamphlets contain more words than that of DR. ROCHESTER, but in some ways possibly serve the purpose in view somewhat better. We shall therefore recommend our correspondents to apply to the Society named, as it furnishes a formed and convenient means of carrying out the excellent design. So far the Society has issued two circulars, each containing four octavo pages. Tract No. 1 is entitled "How to Avoid Contracting Tuberculosis (Consumption)," and Tract No. 2 is headed "How Persons Suffering from Tuberculosis Can Avoid Giving the Disease to Others."

Physicians will at once recognize that this is a "labor of love," and that instead of buying pamphlets they may accept the Society's offer of membership for the sum of one dollar, and get the tracts *gratis*, in such amounts as they can advantageously use. But of course it is understood that the tracts will be furnished upon application to the Secretary whether one is a member or not.

The Secretary is E. LESLIE GILLIAMS, and his address is 806 Walnut Street, Philadelphia.

EDITORIAL COMMENTS.

The General Session and the Section.—At the meeting of the Pan-American Medical Congress, one of the most successful Sections resolved at its first meeting to carry on its section-work during the meeting-hours of the General Congress or General Session. This was in no disrepect to the General Congress, of course, but was necessitated by the amount of work to be done by the section and greater interest in its proceedings. The resolution was faithfully carried out and no one regretted it. The earnest workers wisely preferred work to east wind. According to an old medieval medical writer, east wind is peculiarly prone to produce flatus, and should therefore be carefully avoided!

Limit the Reading of Papers at Least to Twenty Minutes.—One of the Sections at Washington resolutely resolved to limit all speakers to twenty minutes, no vote being allowed to extend the time of anyone. The result was a series of bright, condensed, and interesting papers, the

attention of the audience never flagging and satisfaction expressed by all. Another, perhaps many other Sections, gave "courtesy" to one and so courtesy to all (except the listeners), with the result that some writers read for an hour or two, to the great disgust of everybody. And to cap the climax, some of the hour-long papers were in Spanish! In these cases the punishment most excellently fitted the crime.

The American Medical Association.—By the special committee of the American Medical Association, it has been resolved to recommend to the general business committee of the Association a change of the date of the next meeting of the Association, from the first Tuesday in May, 1894, to the third Tuesday in May.

SOCIETY PROCEEDINGS.

FIRST PAN-AMERICAN MEDICAL CONGRESS,

Held at Washington, D. C., September 5, 6, 7, 8.

(Continued from page 308.)

GENERAL SESSION.

THIRD DAY—SEPTEMBER 7TH.

THE principal address of this session was delivered by MR. ERNEST HART, OF London. He said:

MR. PRESIDENT, LADIES, AND GENTLEMEN: We are told traditionally that Sir Astley Cooper, one of the great surgeons of this century, who remains with us not only as a model of a brilliant surgeon, but an accomplished gentleman, was in the habit of addressing every candidate for a degree from the college with which he was connected, something after the following manner: Gentlemen, you are about to enter upon a noble and difficult profession, and your success will depend principally upon three things: Firstly, upon your knowledge; secondly, upon your continuous industry; and thirdly, upon your moral character. Without the first, no one could wish you to succeed; without the second, industry, you will never be able to succeed; and without the third, strength of moral character, even if you do succeed, success can bring you no happiness. Now, those words might form a very adequate summary, a short text-book of the conduct, private dignity, and etiquet in relation to public affairs, of all medical men; and, one might very well ask whether anything more than that is at all necessary, whether there is any necessity for a detailed and elaborate code when the whole philosophy can be summed up in so few words. And just now in our country some do ask that question, and I think to some extent in this, it has become a question as to just how far it is necessary to add to the simple rules of ethics, which give the conduct of Christian and honorable gentlemen in all professions. Is it necessary to add to this a detailed code of medical ethics or of medical etiquet? That question is one which has been solved. It was held in no doubt until these recent times. But, nevertheless, I think it is clear that never at any time, if there were a necessity for such a code, could that necessity be nearer and more apparent than at the present moment. Under the stress of a developing civilization, with the temptations and difficulties induced by the enormous facilities for advertisement, the enormous temptations for advertising with all the arts of those who make advertising a business, and the profit to tempt the medical man from the ancient bond of modesty and diffidence, there is now the strongest reason for fortifying every professional man against the inroads of modern temptations, by a code so precise, by deductions so exact, so comprehensive, and so far-reaching that he shall never be overcome by such temptations, but shall be able to know at once, and under all circumstances, what is his duty, what is the rule of his profession in any one particular case in which he may be tempted. By possible excuses, which his vanity, his interest, his natural love of prominence suggest to him, he may be tempted to decide a doubtful case in his own favor and against the general good and welfare of the profession as a whole.

Now, I want to say that such a code as this does exist, and exists upon a logical and strong basis, exists for the benefit of the public, at least as much, if not more than for the benefit of the profession; that it is not a trades union business, it is not an elimination of public liberties and rights for the benefit of a private interest, but that it is, on the contrary, a movement which is made far more for the interests of the public in general than for the interests of the profession, and that applies not least, but even more to those regulations of the medical code which have from time to time been stigmatized by the public press as narrow and oppressive, and stigmatized as useless by those who call themselves the bolder and younger spirits among us. But, not even the youngest of us, as you know, are infallible, and I think it is precisely the youngest and boldest which, in this case, are likely to go wrong.

Now, first of all, let me remind you that the medical profession is only one of many professions. We have standing alongside of us the profession of law and the profession of the church. It is interesting, from a universal standpoint, to consider what is the code of the legal profession, why is that code justified and how does it compare with the medical code? Just before I came to attend this Congress, I wrote some legal men concerning some details of the legal profession. One of them said: After all, the general spirit of a code may be summed up in a few words: That, every practising lawyer ought to be a gentleman and do only what is honest and honorable and fair to others, and, if he does not act like a gentleman and is not honest and honorable and true to his profession, honorable men ought to have nothing to do with him. (Applause.) Now, you notice the deduction, that if he does not, honorable men of the profession ought to have nothing to do with him. That is precisely our position to-day. (Applause.) Questions in the bar and with the legal profession are strengthened by this, that the discipline of the bar is absolutely in the hands of the Attorney-General of England for England, and is decided without appeal, so that any solicitor who is guilty, not only of any technical offense against his duty as a lawyer, but any solicitor who is guilty of anything which brings dishonor upon him as a gentleman is frequently not only temporarily suspended and subjected to deprivation of the right to plead, but the right to practise his profession. My friend sent me a case which occurred last June, in which it was decided that a solicitor in a provincial town who had, in virtue of

certain house-property which he held, been a party to immorality, and used the house for immorality, and had left a stain upon his character as a gentleman, and for that he was excluded from legal practice for a number of years, subject to reinstatement upon proof of good conduct. So, the legal profession has a code far stricter than ours, but a code which everyone admits is for the benefit at least as much of the public as of the profession.

Now, let us take one or two other examples of legal etiquet. There are several things a lawyer must not do He may not conduct a speculative suit. That is to say, he may not conduct a suit in which his pay depends on the issue of the suit. Well, that looks like a restriction upon liberty, O, how that word liberty is licensed! Liberty is a blessed word, but compulsion is a more blessed word. (Applause.) That looks like a restriction upon liberty, but if a lawyer is personally and financially interested in the result, and the case goes against him, he is angry with the judge and is apt not to do his duty, because it is his duty to see that justice is secured. So, although it looks like a restriction on the lawyer, it is only right he should have no financial interest in the case he conducts. Many men do. There are here many of what you call shyster lawyers. They are not the men of whom the country is proud. If a man does not regard the code of ethics, honorable men should have nothing to do with him. So with many other elements in the legal code of ethics, which I will not dwell upon.

I will pass at once to the code of the medical etiquet, and I will ask you to consider whether you are of the opinion that you can safely cast aside all the precedents of past experience, all that you may call the case law. That is the question and deductions which have been carefully and deliberately reached in respect to the applications, to the daily applications of medical life of the general principles of ethics. Now, if men abjure the abstract and moral character, no doubt a few abstract and moral laws would suffice for his daily needs. For example, a medical man is prohibited from consultation with quacks. Now, in order to determine the meaning of the word quack, I have looked up Dr. Johnson's defition. "Quack—a boasted pretender to arts which he does not understand; a boasting pretender to physic, one who proclaims his own medical abilities in public places; an artful tricking practitioner in physics." Thus, you see there is no distinction between the quacks who have medical degrees and the quacks who have not. Moreover, no respectable physician should advertise. That is a method of the quack. He is a person who seeks advertisement. This advertisement may be in the way of an interview by a representative of the secular press, or it might be by a published letter, by the description or criticism of some new alleged system of treatment, or it might be by divulging the secrets of the sick-room and reporting without authority of permission on the incidents and course of the illness of the distinguished or notorious somebody, who Dr. ——— is treating. Such arts are in direct contravention of medical etiquet, and deserve the scorn and reprobation of every honorable person as well as every honorable medical man. (Applause.) It is in the interest of the public in general, of the whole community, that the medical profession and every member of it shall be worthy of the confidence of the public, and that the physician shall earn his reputation, not by dishonest means, not by advertisement of himself or his books, not by the prominence accorded to him by the journalist, but by his colleagues of accepted and approved knowledge, and in view of his conscientious and modest application of that knowledge. As to the rule which prohibits the medical man possessing or profiting by any secret remedy: Not only is this an offense against professional morality, but it is a source of great public danger as well. The physician owes his knowledge as well as his capacity for practising medicine to the open communications of by-gone practitioners, and daily he continuously receives such aid from his colleagues. Indeed, it is to their published knowledge and experience that he owes the greater part of his means and ability of practising his art. A new treatment, drug, or medical dogma, is like a doctrine, dogma, or deduction, in theology. The one is for the purpose of aiding the body, for physical salvation, while the other is an aid to spiritual salvation. From traditional law, and in virtue of the mission of the physician or priest, both are alike the common birthright of humanity, and any man who for profit keeps as a secret a new treatment or a new doctrine is a traitor not only to his profession but to all humanity. The physician who trades in or palters with secret remedies is untrue to his obligations, unfaithful to the world, a shame to himself, and a dishonor to his calling. It is only right that he should be treated accordingly under the professional code, and that he should not have a standing equal to the man who is true to his profession, true to humanity, and true to himself. (Applause.) Nor can the alleged value of any so-called secret remedy be held to condone such an offence, for never in the whole history of mankind has there ever been one of these so-called secret remedies which when divulged or discovered by examination has proved to be of the least value.

Next, we are not permitted to consult with homeopaths. This portion of the code of medical ethics may be justified as a principle of elementary morality. How can we believe in their ability, or how can we appreciate the medical capacity or the fitness to undertake the treatment of disease, of the so-called homeopathic physicians, who hold that drugs, which given internally will produce certain symptoms of disease, are the proper remedies for those maladies? For example, we do not believe that medicines that produce skin-reddening are the proper therapeutics for erysipelas, that leucorrhine should be administered for leucorrhea, syphiline for syphilis. We do not agree that all chronic maladies arise from syphilis, sycosis, or itch. How can we, under these circumstances, consult together? It would be impossible for us to agree. Further, we do not believe that medicine acts with an intensity proportionate to the smallness of the dose, or that there is any utility in prescribing in accordance with these principles. What would you think of giving a decillionth of a grain of medicine! A dose so small that it has been calculated that if every being on the globe were to take it once a minute for thousands of years they would not finish a single grain. Again, we could not agree with them that the strength of a medicine increases according to the number of shakes given to the bottle containing it. We hold that such treatment is futile and senseless, and that

to pretend to consult with those who thus designate themselves and who make assumptions so irrational, would be a dangerous farce and would cover, to the great detriment and perilous misleading of the public, a practice which is either a dying delusion or a galvanized fraud with the false mask of respectability. It is true that some who call themselves homeopaths do cure diseases by prescribing physiologic doses, but it is not for us to countenance such fraud and dishonesty, for the homeopath who does this is dishonest. On the other hand, if he prescribes according to the rule of Hahnemann, he gives to the patient that which is valueless. It would be as well to ask a Catholic priest to administer religious consolation to a dying patient in consultation with an agnostic, as to ask a scientific physician to consult with a homeopath. The whole proceeding is dishonest on the one side or the other.

Again, a medical man cannot take charge of the patient of another without previous consultation and approval of the physician who previously had the case in hand, or rather under whose care the patient was at the time. A physician is prohibited criticising or advising a patient on any matter relating to another man's work, except under certain stated circumstances and conditions. The consultant is forbidden under any circumstances to take the place of the physician who called him in. All of this is as much, at least, and perhaps more for the public good than for the good of the profession and of the individual.

Dr. Gihon reported the resolution adopted by the Section on Hygiene recommending the suspension of immigration into the countries of America from those countries in Europe and Asia in which cholera is raging. The report was referred to the International Executive Committee.

Fourth Day—September 8th.

Dr. Garcias, of Colombia, spoke (in Spanish) briefly, explaining why more of his countrymen were not present at the Congress, and offered congratulations and thanks on behalf of his colleagues.

Dr. Ferd. C. Valentine, ex-Surgeon-General of the Honduras Army, and present editor of the *Medical Press*, of New York, gave a pleasant and interesting address as to Honduras and its relations to the American people.

The International Executive Committee's report was read by Dr. Reed, and considered such questions as those of a permanent organization of the Congress and its Sections; resolutions referred from the Sections, especially those from the Sections on Hygiene, Climatology, and Demography; the establishment of National Departments of Health, etc.; the suspension of immigration from cholera-infected ports, etc. From the Section on Hygiene Dr. Gihon reported the following resolutions:

Resolved, by this Section, that the following resolutions be added to the resolutions already adopted and reported to the general session relative to temporary suspension of immigration, to wit:

Resolved, that in the opinion of this Section the thorough disinfection, without discrimination, of every piece of baggage, dunnage, or article of personal effects belonging to the immigrant classes and to crews of immigrant ships, and the exaction of scrupulous cleanliness of all vessels arriving at Pan-American ports should be rigidly enforced at American ports, supplementing and enhancing the protective value of similar treatment at the ports of departure, especially at times when cholera exists in Europe, as a sanitary precaution, second only in efficiency and importance to the temporary suspension of immigration.

Resolved, that it is also the opinion of this section that the habitual and thorough disinfection of all personal effects liable to carry contagion of immigrants to the American hemisphere, and of dunnage of crews of vessels carrying the immigrants from any quarter of the globe, and the exaction of scrupulous cleanliness of all vessels arriving at American ports should be enforced at all times as the most efficient means of greatly lessening the introduction into this hemisphere of the seeds of various contagious diseases, which are now and have been in the past almost constantly conveyed by the immigrant classes and distributed widely among the population of this hemisphere.

Section on General Surgery.

First Day—September 5th.

Dr. John B. Hamilton, the Executive President, delivered an address. He said that the rapid evolution of surgical knowledge is one of the wonders of this remarkable age, and surgeons may fairly claim that their own branch of medicine has kept equal pace with the stupendous advances made by the collateral sciences. A review of the surgical progress of the last decade alone constitutes one of the most brilliant pages of the history of medicine. And yet one must remember that all scientific progress is based on antecedent fundamental facts, discovered by slow, laborious, and painful steps.

The labors of Darwin, Huxley, Herbert Spencer, Pasteur, and Lister, in the last decade, have made possible the practical successes in the present decade.

The subject of surgical bacteriology, which includes the chemical study of microbic products, has still much to disclose, but we already base our practice on the immortal discovery of Pasteur. Bacteriology has added much to our knowledge of tuberculosis, and given more precision to its treatment, but that knowledge is still imperfect, and its treatment far from satisfactory. Much less has bacteriology added to our knowledge of the carcinomata, which still remain one of the mysteries of medicine. We have for years studied the varying departures of tissues from the normal to the abnormal type, and bacteriologists have in vain sought to connect the atypical structure of carcinoma with some bacterial development. The study of embryology and atavism seems at present the most probable avenue to the truth.

What may we hope for the future of surgery?

It seems likely at this day that improvements in technique will continue to occupy the surgical mind until some epoch-making discovery in physiology shall have been made. It is not likely that the present generation of surgeons will witness another discovery as far-reaching as that of Pasteur. We must digest and fully assimilate the discoveries of the bacteriologic epoch; that process will probably fully occupy our time and that of our immediate successors. It is true that we may have

some help from advances in the collateral sciences; transillumination of the body, for example, may be yet fully developed in our time, instruments of precision as aids to hearing and vision may greatly assist us in making our present knowledge useful, but the great outlets to human life, such as carcinoma, in all probability will have their genesis understood only by the surgeons yet unborn. When that time shall have come, carcinoma and tuberculosis will be classed among the preventable diseases. These two affections have cost more human lives annually than cholera or yellow fever, and yet no government has ever set on foot any systematic and regular inquiry into their causation or propagation. It is true that the study of tuberculosis in cattle has been the subject of much attention by the Bureau of Animal Industry, but so far as the human race is concerned little has been done in the direction indicated.

DR. ROBERTS, Chairman of the Section on Anatomy, delivered a short address. DR. EDWARD A. TRACEY, of Boston, Mass., read a paper entitled "A Brief Splint-Technology for Surgeons." The objects of this paper are: to treat in detail of a new material and method used in surgical splint-making, to urge the surgeon to become the maker of suitable splints for cases occurring in practice, and to indicate lines of procedure in apparatus-making.

Material. The basis of the material employed is wood-pulp, made preferably from the crushed fiber of the poplar tree. This is rolled into sheets in such wise that the fibers intertwine in every direction, and loosely, thus giving an increased ductility to the product. These sheets are further strengthened by having a fabric introduced between the layers of the pulp, or by interweaving with the short, crushed wood-fibers, a long jute, or other tough fiber.

These sheets are made of several thicknesses; for convenience I shall designate them by number, each figure representing one millimeter. Thus, sheet 1 has a thickness of one millimeter, sheet 2, of two millimeters, and so on.

The characteristics of this material are stiffness or rigidity when dry, and plasticity with toughness when moist. Its rigidity can be increased *ad libitum* by the use of a silicate solution as a moistener.

Splints for irregular surfaces. A splint cannot be directly moulded over the ankle-joint, owing to the great irregularity of that part. This difficulty can be overcome in several ways. The anterior splint should be cut from sheet No. 1, and applied, after moistening, to the limb, care being taken to keep the outer border in contact with the skin and the superfluous material pinched up between the thumb and forefinger. A bandage should be applied to perfect the moulding of the splint. Again, it is possible to cut away the superfluous material, bring the edges together, and retain them there by a strip of material over the cut edges.

Moisteners. Water, or a stiffening solution, can be used to moisten the material previous to molding. The advantage of water is its omnipresence. With its aid a serviceable splint can be made. Such a splint, however, is liable to be softened by the absorption of perspiration, or, on children, of urine; and for this reason it should be protected by a covering of oiled paper silk, mackintosh, or, best of all, by a coat of varnish. A solution of potassium silicate has several qualities that render it the best of the stiffening solutions experimented with. Any desired degree of rigidity up to brittleness can be given the splint by using a silicate solution as a moistener—the stronger the solution the more rigid the splint. A splint rendered rigid in this wise is not affected by perspiration, nor, indeed, by momentary contact with fluids, as in washing. Another quality, of exceptional advantages in cases of compound fractures is that this solution has strong antiseptic properties. The manner of moistening deserves mention. It is most satisfactorily done by means of a flat paste-brush, applying the fluid used on both sides alternately of the splints, and repeating until the proper amount of fluid is absorbed. Practice enables us to judge the precise amount of moisture suitable for our purpose.

A splint for the spinal column should be cut from sheet No. 1, moistened with the solution of potassium salicylate, and passed once and a quarter times around the patient's body. The position of the patient should be like that when a plaster jacket is used. A sheet wrapped around facilitates the adherence of the splint, the material whereof should be pressed into the hollow of the back.

A light and excellent splint for the forearm, and such as retains the bone in position with ease, is made with this material. A palmar forearm splint is sufficient in most cases.

In the discussion that followed, DR. WAKLEY, of Malone, N. Y., observed that new paper-pulp, which acted like the wood-pulp used by Dr. Tracey, was inferior in this respect, that it could not be folded and bent about sharp angles.

DR. SAYRE, of New York, stated that the splint was very light and very nice, and for many cases very useful, but he would not think the material suitable for spinal supports, because of bending and puckering in of the material when it was wet to fit it to the body. It does not make the exact fitting necessary to give good support to the spine. The fault he has found with all materials he had tried is that while wet they were not sufficiently pliable and elastic to adapt themselves to irregular outlines, and the fit was consequently only approximate. In many cases it is not necessary to have a very good fit, and for such purposes this material is very useful.

DR. MCLEAN, of Detroit, had for years been accustomed to extemporize splints out of folded newspapers, which he had found very useful and always to be had in cases of emergency. He noticed Dr. Tracey passed around a forearm splint, which appeared to be for use in Colles' fracture, and he personally thought that too prolonged retention of splints in this fracture and the extension of the splint too far down upon the hand were detrimental and tended to the production of stiff wrist and fingers afterward, which he thought was to be attributed rather to the splint than to the injury of the bone.

SECOND DAY—SEPTEMBER 6TH.

Morning Session.

DR. JOHNSON read a paper on "Simplicity in Surgery," in which he inveighed against the practice, too frequent nowadays, of adding new and not very useful

details to the already complicated procedure of surgical operations. He would abandon nothing of real utility, but would strip operations of all "useless and cumbersome frills." He contended that simple aseptic means were the best, such as the use of boiling water for disinfecting instruments, provided the boiling went on for a sufficient time; the use of gauze dipped in a corrosive sublimate solution and wrung out, and attention to the ordinary rules of cleanliness. The older and simpler sutures have kept their place. And for hemorrhage, the Esmarch band has proved the most effectual control.

DR. HAINES, of New York, then read a paper on the "Study of Anatomy of the Thoracic Organs by Means of Composite Photography." He had photographed a large series of cadavers, after making certain dissections, and had made composite photographs of these dissections, and taken careful measurements of the relations which the parts bear one to another. He found that a good many of the statements in some of our standard text-books were at variance with the results which he obtained by this process. In many instances the statements in the present text-books are very vague and unreliable, and the points from which measurements are given are so indefinitely stated that no accuracy can be had in determining the exact location of the parts. The paper had particular reference to the location of the heart.

"Observations on the Rotary Lateral Curvature of the Spine, with Special Reference to Etiology and Treatment," was a paper read by DR. TESCHNER, of New York City. The best results are obtained by early treatment. The disease is more common in girls than boys.

Factors in the etiology of the disease, which are to be regarded as of special importance: Hereditary tendency; general temperament, and the condition of the mind and nervous systems; lack of development of the muscular system and general physical condition.

As to the first, frequently I find decided scoliosis in the mothers of girls brought to me for treatment.

Secondly, most girls afflicted are of an apathetic, morose, and lazy disposition, disinclined to play, and commonly silly and staring in expression. There is a lack of coördinating power, which disappears on treatment. If the wrist is extended the elbow is usually flexed. In addition, the muscles are poorly developed, the digestion weak.

An habitual faulty position of the body, such as resting on one foot, or sitting on one buttock, with the shoulders bent forward, so that there is a sagging of the whole body, may lead to a permanent distortion, by causing actual bony and ligamentous changes. Long school hours are a cause.

Treatment. Removal of the causes. Deformities should be mitigated. Frequent baths, and tonics if necessary, with careful regimen were advocated. The patient should be placed in a proper manner, in a chair reaching to the shoulders and supporting the back, with the foot touching the floor. Frequent lying down, with the legs extended and arms fully stretched out, is to be recommended as well as self-suspension twice a day.

Lower habitual scoliases can be obliterated by voluntary muscular effort. No support like a corset should be permitted.

Again, there are scolioses that, unaffected by muscular effort, can be reduced or obliterated by suspension of the patient. In these cases I adopt light and well-cemented plaster-of Paris corsets, while the patients are suspended. As to scolioses when the deformities are fixed, I make use of forcible daily twisting of the spine in compression of the ribs by means of an apparatus described by D. A. Hoffer, of Würzburg.

In the discussion, DR. SCHNAPPS, of Brooklyn, said he thought that cases of lateral curvature required no mechanical support, and that teaching the patients to rely upon their own muscles to hold their bodies upright was very necessary, and that artificial props tended to diminish the power of the muscle by constricting it.

DR. TESCHNER replied that some cases required and some cases did not require artificial support, and that when he can get along without this support he does not employ it, but in some cases it is necessary to use it until the patient develops sufficient muscular power to be able to voluntarily keep the body upright. In many cases they are not able to do this.

DR. GRAHAM, of Chicago, read a paper on "Carbuncles." After an exhaustive review of the subject of carbuncles, Dr. Graham spoke of the methods of treatment. He thought that often subcutaneous suppurative inflammations were called carbuncles, when they were only abscesses. The true carbuncle is necessarily limited in its extent and duration. Palliative means he considers useful if nothing more can be done. Caustics, incisions, etc., are recommended, but he advised the total extirpation of the indurated mass as a tumor would be extirpated. The extirpation should be done early, and the incision should extend just beyond the borders of the induration.

Afternoon Session.

A paper on "Recumbency in the Treatment of Pott's Disease" was read by Dr. JOHN C. SCHNAPPS, of Brooklyn, N. Y.

It is not alone the collapse of a cavity produced by disintegration which is the local determining condition of the deformity of Pott's disease. The softened bone which surrounds for some distance and merges into the seat of actual destruction is squeezed out by longitudinal pressure, bent out by antero-posterior leverage, and pushed out by direct backward pressure. To directly antagonize these deforming forces it is necessary to have a passive spine. Portative apparatuses are limited in their efficiency by reason of the distance and heterogeneous character and mobility of the parts which intervene between their points of application and the lesion sought to be controlled, and are usually applied with a view to maintaining the activity of the spine as a support and a base for muscular exertion. Recumbency means more than simply putting a patient to bed. It implies the retention of the whole spine in the best possible position so that the separate parts remain unchanged or subject to such changes only as the surgeon may make. When the patient is horizontal, the force of gravity which had acted when upright as a deforming agent can be converted into a reforming force. Direct backward pressure can be accurately antagonized. Muscular action and consequent interosseous pressure, now greatly reduced by the general condition of rest, can be overcome by fixation and by less traction than would be required to raise the weight of what were superincumbent parts.

The spine, thus relieved of the performance of all its active functions, and saved from all traumatisms, is placed in the best possible condition for repair. And, what is of great importance, fever and the drain of muscular spasm, pain, and perverted nutrition are met by a state of systemic rest. Clinical experience has demonstrated the truth of these theoretic considerations. The indications for recumbency are: (1) As a routine measure, so soon as a diagnosis of spondylitis has been made or is even probable. (2) In cases of patients wearing braces, with persistent sores, progressive deformity, psoas contraction, acute or increasing abscess, loss of power, pain, night-cries, grunting respiration, inclination to lean on chairs, etc., or any other suggestion by face, attitude, or gait that the proper degree of support has not been secured.

DR. FRANK, of Chicago, read a paper on "Tapping of the Ventricles of the Brain for the Relief of Intra-cranial Pressure." He indicated the methods by which the ventricles of the brain can be reached through the brain, and emptied, for the purpose of relieving these cavities of the products of inflammation, and the brain from the effects of the compression due to the accumulation of abnormal fluids. Under favorable conditions the operation might be done with fair prospect of success.

In the ensuing discussion, DR. GRAHAM, of Chicago, said: The position Dr. Frank takes, I understand, is that all cases of traumatism, or all cases of inflammatory conditions of the brain with one side paralyzed, should be tapped. I think it perfectly proper in cases of paralysis following traumatism to tap the lateral ventricle. In inflammations of the brain, if we suspect abscess, the case is not properly treated by stopping at the dura. We should tap the cavity.

PROF. LAVISTA (in Spanish) expressed general admiration of the presentation of the subject by Dr. Frank. He has come to the practical conclusion that, instead of simply trephining, or simply tapping the ventricle, it would simply be better to perform craniectomy, which would be more conducive to a permanent cure. The removal of the larger section involved is a more permanent way than the other methods suggested.

DR. MARIAN, of Pueblo, Mexico, read a paper on "Suture of the Brachiocephalic Vein, with Report of a Case." The author uses deep interrupted sutures, made of fine catgut, and in the case reported there was no sign of thrombosis or interrupted venous circulation. Last July the author was called to see a man aged fifty-one years, upon whom it was necessary to perform an operation which involved an important vein. Two sutures were passed with a fine needle. Recovery followed.

In the discussion DR. MARCY, of Boston, said the paper just read points to a distinct advance in surgery. Comparatively little has been known of the possibility of suturing veins. I have had but one opportunity, and that was suturing the right jugular in removing a cancerous growth. The operation was performed this year. It seems to me that a continuous Lembert suture would be valuable in these cases, if care is taken not to puncture it. It is surprising how little force is required to control the hemorrhage, and the less pressure necessary to stop the bleeding the better.

DR. LAPLACE, of Philadelphia, read a paper on "Gastrostomy for Relief of Esophageal Stricture." After describing a successful case, he proceeded:

The second case, thirty-two years of age, had lost the power of deglutition; otherwise he was well. There was a stricture of the esophagus. An operation was made, requiring two separate sittings. Food was introduced into the stomach through the opening. It then occurred to me that I might introduce the sound through the stomach up the cardiac extremity; I think it could be introduced through the stomach into the esophagus.

THIRD DAY, SEPTEMBER 7TH.

PROF. WOLFE, of Glasgow, Scotland (Royal Infirmary), demonstrated the transplantation of flaps from the conjunctiva of the rabbit to the human subject. After carefully dissecting the flaps from the conjunctiva he grafted the skin on the back of his hand. It was claimed that these are especially adapted to burns.

The transplanting of skin flaps from distant parts was postponed.

DR. MARCY, of Boston, read a paper entitled "In What Class of Cases is Drainage Required?"

A discussion followed, in which Dr. Marcy's opinion that drainage-tubes ought not to be used in aseptic wounds was supported by several gentlemen, among whom were Drs. Quimby, Prewitt, McCosh, and Laplace. Dr. Marcy concluded the discussion with the remark that "the great secret of the cure in hernia is to operate so as not to use drainage."

SECTION ON OBSTETRICS.

FIRST DAY—SEPTEMBER 5TH.

DR. JOHN O. POLAK, of New York, presented a paper on "The Management of the Hemorrhages of Pregnancy." The hemorrhages occurring ante-partum are 1, bleeding as a symptom of miscarriages; 2, placenta prævia; 3, accidental hemorrhage from the partial separation of a normally-placed placenta and ectopic gestation.

Hemorrhage as a sign of miscarriage, when very slight, may be controlled by rest in bed, suppositories of morphia and atropia, ʒj. doses fld. ext. of viburnum, or gr. iv. pill of solid extract. In more severe cases with abortion inevitable, cervical softening, dilatation, and the ovum separated, everything being aseptic, the cervical and vaginal tampon is to be recommended, to empty the uterus and secure firm retraction.

Through a Sims speculum with anterior lip of cervix fixed, carry strips of iodoform gauze into the cervical canal through the internal os, then pack anteriorly, posteriorly, laterally, and finally against the cervix, filling the whole vagina with gauze.

Clinically a prævia is where the placenta has an attachment in the lower zone and the cervix, from which it is detached during canalization. Before viability, the diagnosis made, with the fetus dead and implantation central, with hemorrhage, the indication is to empty the uterus. After viability, act with the occurrence of the first hemorrhage. It is not good obstetrics to allow the patient's strength to become exhausted by repeated or continued bleeding, not to speak of the nervous strain she sustains. Hemorrhage occurring and with the cervix closed we should tampon with iodoform gauze at the

end of eight to ten hours, and when the gauze is removed douche with an antiseptic. The cervix in most cases will admit one or two fingers. With this amount of dilatation turn by the Braxton-Hicks method, and bring down a foot, which acts as a most efficient tampon. This method, in my opinion, is superior to either the method of Barnes or the use of internal version.

In accidental hemorrhage from partial separation of a normally-placed placenta, rapid dilatation of the cervix is indicated manually, or if the portio vaginalis be effaced, the bloody method; then rupture the membranes, and deliver rapidly either by forceps or version. Remove the placenta immediately and tampon the uterus with iodoform gauze to control bleeding. Craniotomy may be resorted to if the fetus be dead or non-viable.

I condemn ergot in these cases before delivery, as it causes spasmodic action and tendency to the formation of stricture at lower segment.

PROF. MANUEL GUTERIER read a paper (in Spanish) entitled "A Comparison Between the American and European Pelves. Practical Consequences from the Peculiar Mexican Pelvis."

SARAH H. STEVENSON, M.D., of Chicago, contributed an article entitled "A Study of Placenta Prævia, Especially the Causes of Hemorrhages."

DR. HUGH HAMILTON, of Harrisburg, read a contribution entitled "The Application of Graphics to the Fetal Heart Sounds," with a demonstration of the method advised and a consideration of its practical application in doubtful pregnancy.

In the discussion that followed DR. DE SAUSSURE, of South Carolina, asked the gentleman who read the paper on the Mexican pelvis if there have been any observations made in regard to the forms of the heads.

In answer DR. MANUEL GUTERIER said there is no corresponding deformity between the Mexican head and that of other nations, although there may be in the Mexican pelvis. The diameters of the head are of the usual dimensions. I would like to emphasize the fact that dimensions of the pelvis and the forms of the soft parts are peculiar to the Mexican pelvis, but there is nothing peculiar in the diameters of the fetal heads.

DR. DE SAUSSURE, of South Carolina, asked Dr. Stevenson if the hemorrhage of placenta prævia comes from veins.

DR. STEVENSON, of Chicago: I think we frequently have arterial hemorrhage, and I stated in my paper one case where it was almost direct. When the placenta is high, the uterine artery runs a very tortuous course, and when the placenta is placed low the arterial supply is almost direct from the uterus. There is one question I should like to ask Dr. Polak regarding the use of iodoform to any great extent, and if so used whether it does not cause iodoform poison.

DR. POLAK, of New York: My use of iodoform has been quite large; I have employed it in sixty-eight cases of hemorrhage. In six of these I have left over one-half dram, nearly sixty grains, of iodoform, and there was no absorption to cause any iodoform poison. The iodoform in those cases does not act directly, but is dissolved and simply acts as an antiseptic. It had really no direct effect, acting simply to keep the discharges back.

DR. HARRIS, of New Jersey, asked to what extent arterial depletion of the mother by loss of blood may not cause fetal asphyxia, or whether such cases occur when there has not been arterial depletion of the mother. We have reason to believe that in cases of placenta prævia this is a very considerable factor in increasing the death-rate of children as well as to render them more likely to be stillborn.

DR. STEVENSON, of Chicago, thought that in fetal asphyxia the heart-beats would be accelerated at first, and would be retarded at the close. At death, heart-beats would occur more slowly. Axphyxia is certainly a lack of blood-supply to the nerves of the child. That at first would cause acceleration. The action of the poison around the heart would be certain to produce very rapid action, and at the close retard it.

DR. HARRIS, of New Jersey, asked to what extent incisions have been made in the cervix to facilitate labor.

DR. POLAK, New York, in reply said that the operation of incising is recommended by Dührssen. In the speaker's experience it has proved to be very successful.

DR. DEWEES, said that in his case he had used the lancet and chloroform, and that at this stage chloroform had always resulted in post-partum hemorrhage. I have been teaching that chloroform is not to be used until the head is through the os. If the patient drops off to sleep and the pains come on with strong regularity, in those cases in which we need immediate delivery in the interest of the mother and child, I think it is well to use the lancet.

DR. DEWEES, of Kansas, said that the cases in which he used chloroform are entirely different from those in which the lancet is used. I use the lancet when it is necessary to produce quick delivery. Chloroform produces an easy delivery, and there is no danger when the pains and contractions are strong and active and the patient in a healthy condition. Under these conditions I have given quite large doses. You will be surprised what good results it will bring immediately.

SECOND DAY.—SEPTEMBER 6, 1893.

"The Status of Obstetrics in General Practice," was the subject of the paper by DR. ELIZA H. ROOT, of Chicago. She asked why child-bearing is so often followed by health-ruining results.

The conditions which prompt the patient to seek advice of the gynecologist belong to one of two classes of causes or to both combined. I. Traumatisms. II. Inflammations, due largely to septic infection at or during the lying-in period.

The causes which produce the conditions may be traced to ignorant and careless practice; (*a*) of the accoucheur, physician, or midwife, or of the patient herself, or in the care of the lying-in patient. The physician assumes the responsibility of the lying-in chamber without sufficient clinical training and experience. Carelessness and ignorance on the part of the patient frequently put the skill of the physician to a severe test. The physician will know nothing of a case of nephritis with albuminuria until called to a case of eclampsia, that with treatment and care might have been avoided. Constipation during gestation is a frequent source of danger to the lying-in period. A case proved to me how serious the consequences when the ignorance of the patient is combined with the ignorance and careless-

ness of the physician. It is the physician's duty to teach his patients the importance of seeking timely advice and to duly warn them of the consequences of not doing so; for in no branch of medicine will an accident or fatal outcome prove more disastrous to the physician. The surroundings and the nursing of the patient should not be left out of the physician's code of duty. The practice of paying one visit after delivery that prevails in some parts of our country is reprehensible.

DR. J. H. CHESTNUT, of Philadelphia, next considered the question of "The Induction of Premature Labor." The groups of cases whose circumstances may call for the operation for the induction of premature labor include: First, cases of contracted pelves which would render labor at term dangerously difficult to the mother, to the child, or to both; second, cases of maternal disease which progressively endanger the life of the mother; third, cases in which in previous pregnancies the child has died in the latter weeks of gestation; fourth, cases of hopeless disease of the mother, for the sake of the child; fifth, cases in which the child is known to be dead; and, sixth, cases complicated by the presence of ovarian, bony or malignant tumors, or by atresia of any part of the normally distensible canal.

The relative number of markedly contracted deformed pelves is very small; in a private obstetrical practice of more than twenty years the writer had met but one case with a conjugate diameter at the brim of less than two and one-half inches; but cases of lesser contraction where the same diameter measured from three to three and three-fourths inches, or where there appeared to be a slight degree of lessening in all diameters, were not so uncommon.

The writer believes that in cases of deformed pelves where the antero-posterior diameter at the brim is from two and three-fourths inches to three and one-fourth inches, and in cases of justo-minor pelves, where the same diameter is three and one-half inches—labor should be induced before term, when the conditions described are recognized in due time. The difficulty of diagnosis at the proper time is the obstacle to the more frequent employment of the operation in these cases.

DR. A. J. C. SAUNIER, of Chicago, next read a paper on "Aids to Easy Parturition."

Aids to easy parturition should be considered and their application begun early in life. Care is to be exercised in young women at the time of menstruation to prevent undue congestion and to secure free catamenial flow. After impregnation, diet may influence the amount of suffering undergone at the time of childbirth. All pelvic troubles, especially inflammations, should be corrected during the period of gestation, and we should abridge the first stage of labor by securing frequent and strong uterine contractions, by means of massage of the abdomen and digital assistance in dilatation of the os uteri.

In the ensuing discussion, DR. STEVENSON, of Chicago, said he should like to reinforce the arguments and statements of Dr. Root as to the number of so-called obstetricians and midwives in this country. The facts which were so well brought out in her paper, that obstetricians and midwives are not supervised here as they are in the old country, and the harm done to obstetrical science in this country by midwifery, presents a very grave question. I think this body ought to take some measures to prevent the spread of incompetent midwifery among us. There are two things essential for the good of obstetrics: First a *good* obstetrician, and second, a thoroughly well trained nurse. It occurs to me that as an authoritative body we should at least use our influence against the licensing of careless or incompetent midwives.

DR. UPSHUR, of Richmond, Va., said that one of the trying evils of this day is carelessness in the attention of midwifery cases. I try to emphasize with my own patients the need of an early engagement for attendance, and I try to obtain as thoroughly as possible all information. I make it a matter of conscience to visit the patient repeatedly, and soon after the engagement obtain knowledge of all previous conditions—whether the patient has been a subject of dysmenorrheal trouble or not; as to her general health; profuse flow at the time of menstrual period; the patient's general habits, sleep, exercise, conditions of physical trouble, constipation, etc. I believe the secret of safely bringing forth the child is the attention paid to the mother. I am satisfied that the man who fails to watch carefully the condition of the kidneys, the existence of albuminuria, or of any small puffiness of the hands or feet, which would lead to trouble, or a tendency to persistent headache and wakefulness, will sometimes lose an excellent opportunity to prevent trouble when labor comes on. I agree very fully with Dr. Root as to the value of cleanliness. The patient should not receive visitors until she is in such condition as to admit of this without being fatigued. I am sorry to say that a large number of nurses are negroes, and they have certain ideas in regard to the management of the child which are hard to overcome, and very often with the utmost care the physician will find that something has been done to the detriment of the patient without his knowledge. It requires the utmost care and the most rigid scrutiny to see that our instructions are carried out. If this is not done, these meddlesome women practice their methods, and the patient will probably have to go through the rest of her life an invalid in consequence.

I had a case where a midwife used a large syringe upon every patient, producing septicemia and bad lacerations. Such treatment ought to be met with a term in the penitentiary. Any woman applying for a license for midwifery may get it for a small fee. This ought not to be encouraged. Often we are called to undo the ills which follow in the train of these meddlesome, inefficient midwives.

Dr. H. HAMILTON moved that a resolution be passed to take some measures toward improvements in midwifery in this country.

The Chairman appointed as a committee to take charge of the matter, Drs. Root, Upshur, Chestnut, Stevenson, and Guterier.

Dr. GUTERIER, of Mexico, continuing the discussion, said that in Mexico it was proposed that there should be a requirement of two years' preliminary education, and then three years of more technical education, requiring in all, a five-year term for educatien.

"The Mechanism of Labor," by JACOB CHASE RUTHERFORD, M.D., of Providence, R. I., was the next paper read.

The theory of the mechanism of labor, as advanced by all ancient and many modern obstetrical writers, is entirely without foundation. The ground taken that the parturient canal is curved cannot be maintained for a moment when we consider the anatomy of the parts, the changes that take place during pregnancy and the phenomena of labor. . . . The mechanism of labor, briefly, is as follows: In head presentations, occipito-anterior, the head descends in the axis of the uterus in a straight line, until it reaches the trough of the levator-ani muscle, when rotation begins; continuing to descend in the same line, it reaches the bottom of the trough, which is the floor of the pelvis. By this time rotation is completed, and now begins the hardest part of the labor, for the head having reached the floor of the pelvis, cannot go any further, but must change its direction and pursue a course at right angles with the one it has been following. This change in direction is brought about by extension of the head into the vaginal canal. As the head extends, the body descends, and by the time the head is fully extended it has passed the vaginal orifice, and the shoulders are at the utero-vaginal angle. They pass the angle by a lateral bending of the body and are followed by the hips and legs.

In occipito-posterior cases, labor is prolonged by the impossibility of further flexing an already fully flexed head, and the perineum has to be enormously distended before the head can be delivered.

In face-cases mento-posterior delivery is impossible because the head cannot be further extended, and the stiff, straight fetal body cannot be bent around the angle. A knowledge of the mechanism of head-cases embraces a knowledge of the mechanism of other presentations.

The deductions to be drawn from the above theory are: first, the parturient canal is angular, not curved; second, when the presenting part has reached the bottom of the trough in the pelvic floor, rotation is quite complete; third, flexion and extension take place at the utero-vaginal angle; fourth, in the high forceps delivery traction should be made in the line of the uterine axis, and in the low forceps, delivery in the line of the vaginal axis.

"Obstetrics Among Negroes of South Carolina," was an interesting communication by DR. P. GOURDIN DE SAUSSURE, of Charleston. The negress differs from her white sister. I found the average weight of 57 female children at birth to be 7.50 pounds (48 boys, 8.25). Menstrual life begins earlier. From several hundred observations I estimate it to be about the thirteenth year. Thirty-three cases, where the age was certainly fixed, gave 13.10 as the average; this is a full year earlier than Emmet's "average menstrual age," 14.28. A possible explanation of this precocity may be the early use of the sexual apparatus. The childbearing period is longer with the negro than the white, for the average age at the menopause is about 49. In 43 cases, where the age could be proved, I found it to be 48.6; more extended observations, I believe, would give us 49+, for I have delivered several who claimed to be over 52; and in a midwife's book I found records of three delivered at 53. On this point the following figures speak: 19 primiparæ gave us an average age of 18.2, and 7 multiparæ having twelve or more children each had an average age of 38.8.

As to the menstrual flow its duration was 4.2 days in 53 observations; the amount, however, is less than in the whites. As a rule, the negro is remarkably free from menstrual irregularities. Amenorrhea, dysmenorrhea, and menorrhagia are rare amongst them, and when found are almost always due to anatomical defects or lesions. The mulatto is an exception to this rule. The negro is more fruitful than the white—that is, their families are larger; 107 observations on this point give us 5.8 children to each. Of the 107, 19 were primiparæ and 7 multiparæ, with 12 or more full-term pregnancies. The ratio of twins was in 14,320 colored births, 9.63 per thousand, and in 7140 white births, 9.52 per thousand.

The negro is very free from the diseases of pregnancy. I have in eighteen years never seen a case of hyperemesis, icterus, or chorea; eclampsia seems to be an exception, and in the last five years has become more frequent. In 11,074 colored pregnancies I found 47 deaths from eclampsia, while in 6044 white pregnancies I found 19 deaths from the same cause. Estimating one death to two recoveries, I find that the ratio of cases to pregnancies is more than 1 to 500, Galabin's and Kleinwacher's estimate, but not much over Parvin's, 1 to 300. As the negro does not take into consideration an abortion occurring before the fourth month, it is hard to speak on this subject. In 37 patients I found but 3 who had not aborted, and the other 34 had had between them 80. In five years there were reported to the board of health 251 abortions in negroes, and only 84 in whites. These figures do not show the hundreds of abortions of an earlier date than the fourth month. Causes of abortions are chiefly syphilis, from which 75 per cent. of the Africans of Charleston suffer either by inheritance or acquisition. Other causes are medicines taken for the purpose of producing the result.

Labor in the negro is a simple act begun and finished without fear. The nervous disturbances so common in the whites are never seen in the negro. Their labors are shorter; the average duration, in primiparæ, in 13 cases was 6.9 hours; in 8 multiparæ, 2.15; but aside from looking on the act as a purely physiological one there is this fact to be borne in mind: the African pelvis is larger. These measurements, external pelvimetry, speak for themselves—17 cases:

Circumference	92
Between spines, antero-superior	26
" widest parts	29
" trochanters	33
External conjugate	21

The negro is very free from puerperal fever or septicemia. In 14,600 pregnancies, 14,358 at term, I found but 57 deaths from puerperal diseases, and this amongst a race that has not an idea of cleanliness.

"Uterine Compression," by DR. JOSÉ MARIA DE ITA, of Pueblo, Mexico, was the next communication:

The author, who for the last ten years has been in charge of the Maternity Hospital of the city of Pueblo, gives credit to Dr. Juan Maria Rodriguez for having first introduced and practised uterine compression in Mexico. He is perfectly satisfied of its great utility as an aid in the production of uterine contraction. He practises the operation in the following manner:

The woman lies flat on her back, the operator stands by her side, extends his arms, and presses the hands

with the two thumbs together over the abdomen immediately above the fundus uteri; at first only slight digital compression is made, slowly increasing the force, imitating the rhythmical contraction of the uterus. It is necessary sometimes, he says, to continue the pressure steadily in order to terminate the delivery at once.

The indications for uterine compression he groups thus: 1. In all cases of uterine inertia. 2. To help the traction made with the forceps. 3. To expel the trunk when the head of the child has already been born, either by Nature's forces or by traction; in this last event, with the uterine compression one avoids the necessity for further traction on the head, or inserting the finger in the axilla to draw out the rest of the body. 4. To hold the head bent after the expulsion of the trunk, and thus helping to its birth, in a case of feet-presentation. 5. To overcome the resistance of the perineum and avoid the application of forceps. 6. To fix the head in the superior strait in cases when the application of delivery forceps are necessary, or when the use of craniotomy forceps become a necessity. 7. To facilitate the expulsion of the placenta in cases of hemorrhage. 8. To aid the utetus in throwing out the clots retained in its cavity, should a secondary hemorrhage take place.

The author says that in case the uterus loses the power to contract, this mechanical compression will take its place.

When the accoucheur has no assistant with him, he ought to practice the operation with only one hand aided by the forearm, and the other hand used to support the perineum.

"A Method of Performing Rapid Manual Dilatation of the Os Uteri, and Its Advantages in the Treatment of Placenta Prævia," by PHILANDER A. HARRIS, M.D., of Paterson, N. J., was read by the author. A history of eight successful cases was given embracing the author's entire experience in the management of placenta prævia. The method of dilatation was shown, and is to be illustrated in a published report by the aid of ten photo-engravings. The undilated os in placenta prævia, can, under chloroform or ether anesthesia, be enlarged to a circumference of ten to eleven inches in from fifteen to twenty-five minutes; thus rendering it easily possible to effect rapid delivery of child without waiting for the development of labor, or of employing more tardy and inefficient methods of dilatation to any degree desired by the operator.

In the discussion, DR. BRIGGS, of New York, said: Dr. Harris's theory is, I think, the best way in which we can treat placenta prævia. As soon as we can in any way dilate the cervix we ought to do so, because in that way we save many lives. That was made clear years ago by Hirsch. Referring to the rings which the doctor has presented, I would say that they are certainly a very ingenious device. Now everybody knows that we have greater strength in our flexor muscles than in any other muscles. Admitting all this, there is only one thing which might be a little adverse. These springs are composed of a series of rings, which are rather sharp.

DR. HARRIS: These coils represent the os uteri. There is nothing but the hand employed in this operation.

DR. BRIGGS: I think it is an excellent way of dilating the cervix.

DR. HARRIS: I am a little sorry that some of the doctors present did not bring up the Braxton Hicks method.

THIRD DAY—SEPTEMBER 7TH.

"Recent Surgical Advances and their Relation to Conservative Obstetrics," by DR. W. REYNOLDS WILSON, of Philadelphia, was then presented. In view of the fact that the science of obstetrics is the most stable of medical sciences in which fixed mechanical laws largely determine both the event and the conduct of parturition, the influence of modern surgery modifying obstetrical practice is unexpected. This influence is observed in the present treatment of abortion, ectopic gestation, dystocia, in contracted and deformed pelves, and septicemia.

The operations which have become recognized obstetrical procedures in these conditions are: in abortion, curetting in order to remove every trace of decidual tissue, irrespective of symptoms of retention; in ectopic gestation, the removal of the gestation sac as soon as the diagnosis has been established, irrespective of the viability of the fetus; in impeded labor, Cæsarean section and symphysiotomy; in septic infection, curetting and drainage, by means of gauze; celiotomy for peritonitis, and supra-vaginal hysterectomy for lymphatic infection of the mucosa.

Surgery deserves the lasting praise of the profession for the scientific treatment of tubal pregnancy, no surgical procedure being too radical for this condition, but of all these procedures the active treatment in abortion and in septicemia and the substitution of symphysiotomy for the forms of treatment formerly recognized in dystocia from contracted pelvis, are to be questioned.

DR. HENRY J. GARRIGUES, of New York, read a paper on "Symphysiotomy." When the symphysis and subjective ligaments are cut, the limbs bent, and the iliac bones pulled apart, a separation of 7 cm. (two and three-quarter inches) between the ends of the pubic bones is easily obtained without injury to the ilio-sacral joints. The head enters into this gap, and all diameters of the pelvis are considerably increased. The distance between the center of the promontory and the end of the pubic bones, at the safe distance of 7 cm. (two and three-quarter inches), gains 14 mm. (over one-half inch), the other diameters from 17 to 35 mm. (three-quarters to one and one-half inches).

Symphysiotomy is indicated in a flat pelvis with a true conjugate ranging between 67 and 88 mm. (two and five-eighths to three and one-half inches), but it is difficult below 7 cm. (two and three-quarter inches). In a generally contracted pelvis the upper limit may be extended to 10 cm. (four inches), and we should cautiously approach the lower limit. Other indications, with which it has been performed, are pelvic tumor, mento-posterior face presentations, if the chin cannot be rotated forward, occipito-posterior vertex presentation with impacted head; and it has been proposed in cases of absolute coarctation of the pelvis (*i. e.*, below 5 cm.—two inches) with dead child, in order to facilitate craniotomy and embryotomy. The sacro-iliac articulations must be movable. There are two chief methods—the subcu-

taneous (Morisani's) and the open (Pinard's). The child may be left to be expelled by uterine contractions, or removed with forceps, or turned and extracted. Considerable lesions of soft parts have occurred even in the hands of first-class operators. In many cases the hemorrhage has been profuse and sometimes difficult to check. Most children are more or less asphyctic, and in some there has been fracture of the skull. In lying-in hospitals and private practice of specialists it should take the place of craniotomy on the living child and induction of premature labor, in which the infantile mortality is over 43 per cent.

Cæsarean section should be limited to cases that lie beyond the domain of symphysiotomy. Symphysiotomy has several times been successfully performed twice on the same woman.

Dr. John P. Upshur, of Richmond, Va., next discussed "The Therapeutic Application of Chloroform in Labor."

"Induction of Labor and Accouchement Forcé in the Prophylaxis of Eclampsia," by Dr. Charles Jewett, of Brooklyn, N. Y., was the next paper read.

Whatever room there may be for difference of opinion with reference to the etiology of child-bed eclampsia and the nephritis of pregnancy, it is impossible to lose sight of the fact that the ultimate cause of the trouble is the presence of the child *in utero*. So long as the cause remains, our resources either for the treatment or prevention of puerperal convulsions are at most an uncertain reliance, and too often prove wholly futile. A pregnancy-nephritis once established, the kidneys never regain their normal condition while the pregnancy continues. Dietetic, diaphoretic, and cathartic measures are of great value as temporary expedients, but they do not cure.

The extra tax upon the crippled kidneys increases rapidly in the later weeks of gestation, and the danger grows with the growth of the child. The woman is never free from the possibility of a sudden explosion of uremic symptoms. On the occurrence of convulsions the gravity of the condition is enormously increased, and with each succeeding attack it becomes less and less amenable to treatment. After labor, on the other hand, the nephritic symptoms subside, and prompt recovery is the rule. Convulsions in most cases cease with the birth; the attacks seldom begin the post-partum period, and in any event they yield more easily to ordinary remedial measures in the puerperal than in the pregnant or parturient woman.

The chief desideratum, therefore, in the prophylaxis of puerperal eclampsia is the evacuation of the uterus. The writer believed that under modern methods a more aggressive policy is justifiable in the prevention of eclampsia than is generally pursued. It is difficult to formulate definite rules, but in general after the full period of viability little reliance should be placed on other than obstetric measures. In the presence of any but the milder forms of nephritis, immediate and rapid termination of the pregnancy offers the best prospect for both mother and child. The indication is especially urgent in the last month of gestation, when the child has little to gain and the mother frequently much to lose by delay.

Under the methods formerly employed the induction of labor was a difficult and tedious undertaking. With the intra-uterine injection of glycerin, recently introduced by Pelzer, uterine contractions may be set up at will and the birth terminated with rapidity and safety.

Labor begins immediately, as a rule, and is actively established within two hours. The intra-uterine injection of glycerin acts not only to inaugurate the pains, but in greater or less degree to maintain them. Its effect in many cases seems to persist to the close of the third stage if well retained. To act at best advantage the glycerin must be carried high up toward the fundus, must be widely diffused between the membranes and the uterine wall by gradual injection, and its too rapid escape prevented by keeping the patient in the latero-prone position. In many cases no further interference is called for. In imminent danger of convulsions, if the labor is not promptly terminated, it should be completed by manual dilatation of the cervix under chloroform, and resort to forceps or version. Under a rigid asepsis, and with avoidance of lacerations, accouchement forcé is a safe and conservative procedure. Manual dilatation should not be undertaken before the supra-vaginal portion of the cervix is obliterated. In simple cases it is a harmless interference which may save hours of labor and continued danger. In difficult cases with a rigid cervix the operation is even more urgently indicated and is safe, provided sufficient care is used. From ten minutes to two hours will usually suffice to complete the dilatation and terminate the birth. The total length of labor will seldom exceed twelve hours; in emergency, may be reduced to five or six.

The last paper read was entitled "Contributions to the Study of Puerperal Septicemia," by Dr. Antonio Jose Amadeo, of Maunabo, Porto Rico. It was a résumé of the twenty years of obstetrical experience of the author in the town of Maunabo, island of Porto Rico. He says that until lately a physician was there very seldom called to attend a case of confinement, and that puerperal infection is much more frequent in the towns, on account of bad hygienic conditions, than in the country. He holds the opinion that women of a lymphatic temperament are more liable; chronic metritis and leucorrhea are also contributing factors; anemia, and all the manifestations of lymphatic cachexia are unfavorable signs of the prognosis.

In regard to diagnosis, he says that paludal fevers sometimes make their appearance immediately after parturition, but sulfate of quinin settles the doubt. Sleeplessness, nervous disquiet, and ill-smelling discharges are alarming symptoms.

His plan of treatment consists in local antisepsis to reduce the hyperthermia, to open and disinfect abscesses, sustain the vital forces, and combat peritonitis should it make its appearance.

NEWS ITEM.

The American Orthopedic Association will hold its seventh annual meeting at St. Louis, September 19, 20, and 21, 1893.

The following program has been arranged: "The Embodiment of an Idea," Presidential Address, by Dr. A. J. Steele, of St. Louis; "Tuberculosis and the Mind

Cure," by Dr. Ansel G. Cook, of Hartford; "A Case of Fragilitas Ossium, exhibiting over One Hundred Broken Bones," by Dr. Wallace Blanchard, of Chicago; "Congenital Deformities," by Dr. De Forest Willard, of Philadelphia; "A Case of Deformity of the Lower Limbs, with Spina Bifida," by Dr. William J. Taylor, of Philadelphia; "Congenital Absence of Both Clavicles, with Rotaro-lateral Curvature—Specimen," by Dr. A. J. Steele, of St. Louis; "A Case of Congenital Dislocation of the Hips—Patient," by Dr. A. J. Steele, of St. Louis; "Some of the Uses of Continued Extension," by Dr. Henry G. Davis, of Everett; "Historical Notes of the Use of Traction in Diseases of the Joints," by Dr. A. B. Judson, of New York; "The Value of Traction in the Treatment of Joint Disease," by Dr. H. L. Taylor, of New York; "The Value of Traction in Hip Disease as Investigated by Experiment," by Dr. E. H. Bradford, of Boston; "Exhibition of New Traction Mechanism for Hip Splints, with Remarks," by Dr. L. A. Weigel, of Rochester: "A Modification of the Long Traction Splint for Hip Disease, Designed to Provide a Light Apparatus for Little Children," by Dr. Augustus Thorndike, of Boston; "The Question of Excision of the Hip-joint for Tubercular Disease, and the Results of the Operation," by Dr. Harry M. Sherman, of San Francisco; "Cases of Osteo-sarcoma Simulating Tuberculous Hip-joint Disease," by Dr. A. J. Gillette, of St. Paul; "Acute Epiphysitis," by Dr. E. G. Brackett, of Boston; "High Temperature in Chronic Joint Disease," by Dr. Robert W. Lovett, of Boston; "Treatment of Abscesses and Sinuses," by Dr. A. M. Phelps, of New York; "Treatment of Abscesses Caused by Diseased Joints," by Dr. H. G. Davis, of Everett; "The Etiology of the Deformities of Knee-joint Disease," by Dr. A. M. Phelps, of New York; "The History of the Treatment of Tumor Albus of the Knee," by Dr. J. D. Griffith, of Kansas City; "A Contribution to the Treatment of White Swelling of the Knee," by Dr. A. B. Judson, of New York; "The Value of Fixation in Knee Disease," by Dr. George W. Ryan, of Cincinnati; "The Value of Traction in Tumor Albus of the Knee," by Dr. E. H. Bradford, of Boston; "A Splint for Making Traction in the Line of Deformity in Knee-joint Disease," by Dr. Robert W. Lovett, of Boston; "Exhibition of the Ideal Knee Splint, with Remarks," by Dr. John Ridlon, of Chicago; "Exhibition of a New Knee Splint—its Action and Advantages," by Dr. A. E. Hoadley, of Chicago; "The Operative Treatment of Knee-joint Disease," by Dr. De Forest Willard, of Philadelphia; "Excision of the Knee in Young Adults—a Study of Twenty-nine Cases," by Dr. C. L. Scudder, of Boston; "The Advantages of the Gradual Reduction of Flexion of the Knee due to Tumor Albus," by Dr. Augustus Thorndike, of Boston; "Forcible Correction of the Deformities Resulting from Knee-joint Disease," by Dr. J. E. Goldthwait, of Boston; "Internal Derangement of the Knee-joint," by Dr. L. A. Weigel, of Rochester; "The Mechanical Treatment of Osteo-arthritis of the Knee," by Dr. H. L. Taylor, of New York; "The Treatment of Injuries in and about the Knee by Massage," by Dr. Benj. Lee, of Philadelphia; "The Mechanical Treatment of Light Cases of Knock-knee," by Dr. Florian Beely, of Berlin; "The Manual Treatment of Bow-legs and Knock-knee," by Dr. Samuel Ketch, of New York; "Observations upon the Etiology and Treatment of Scoliosis," by Dr. A. E. Hoadley, of Chicago; "The Treatment of Lateral Curvature by Pressure Correction and Gymnastics, with Lantern-slide Illustrations," by Dr. L. A. Weigel, of Rochester; "Exhibition of the Paper Jacket, also of an Apparatus for Recording Rotation in Lateral Curvature," by Dr. L. A. Weigel, of Rochester; "Cast Correction in Connection with Jacket Construction," by Dr. Bernard Bartow, of Buffalo; "Demonstration in the Making of Ideal Leather Splints," by Dr. A. J. Steele, of St. Louis; "Observations on Pott's Disease, with Particular Reference to the Principles of Treatment and their Application," by Dr. Royal Whitman, of New York; "The Cause of Flat-foot," by Dr. Newton M. Shaffer, of New York; "A Double-lever Stretching Apparatus for Club foot," by Dr. T. Halsted Myers, of New York; "Bone Operations for the Correction of Club-foot, based upon an Analysis of 293 Operations by 100 Operators," by Dr. H. A. Wilson, of Philadelphia; "A Case of Adult Club-foot," by Dr. C. C. Foster, of Cambridge; "A Case of Club-hand, with Result of Operation," by Dr. R. H. Sayre, of New York; "Exhibition of a Splint-opener for Plaster-of-Paris Splints, also other Simple Devices," by Dr. Harry M. Sherman, of San Francisco; "Exhibition of an Orthopedic Bed," by Dr. L. A. Weigel, of Rochester; "Exhibition of the Improved Stretcher Splint."

CASES OF HYSTERIA IN MEN[1]

BY HOWELL T. PERSHING, M.Sc., M.D.,
OF DENVER, COL.;
PROFESSOR OF NERVOUS AND MENTAL DISEASES AND MEDICAL JURISPRUDENCE IN THE UNIVERSITY OF DENVER; PHYSICIAN TO ST. LUKE'S HOSPITAL; NEUROLOGIST TO ST. JOSEPH'S HOSPITAL AND TO ST. ANTHONY'S HOSPITAL.

IT is gradually being shown that hysteria is not so rare in men as was formerly supposed. Not very long ago the proportion of male to female hysterical patients was said to be about one to twenty, but Dana, in his recent text-book, estimates it as one to four. My own experience makes me believe that the latter proportion is near the true one, and that the hysteria of males is much oftener mistaken for other diseases than is the hysteria of females.

A diagnosis of hysteria, however, should always be made with caution, and we must keep in mind a clear idea of what is sufficient to justify it.

If a patient presents symptoms that do not correspond with those of any other functional disease, and if thorough examination fails to discover any organic disease there is a certain probability that the affection is hysterical. But reliance on the diagnosis by exclusion alone is dangerous. Cases of multiple sclerosis and even certain cases of muscular atrophy have by this method been mistaken for hysteria. If, now, in addition to the probable exclusion of other diseases, we find evidence of a predisposition to hysteria, the diagnosis is materially strengthened. The predisposition may be hereditary or it may appear only in the patient's personal history, as acquired through disease, injury, or a drug-habit. Mitchell speaks of injuries of the nerve-trunks making the strongest men hysterical, and the hysterical form of traumatic neurosis has lately become familiar. In one of the cases I report the abuse of cocain seemed to predispose to hysteria; and in another of my cases, not reported, the prolonged use of chloral had, apparently, a profound effect of the same kind.

The most essential characteristic of hysteria is the occurrence of symptoms, of which the exciting cause is purely mental. This susceptibility to morbid suggestions, and the consequent whimsical variety and changeableness of the symptoms, are often clearly seen, as in the first case here reported. But in severe cases, or those of long standing, this susceptibility may not appear on the surface, and then hysteria usually reveals itself most clearly in characteristic seizures. These seizures are light or severe. The light ones are the familiar laughing and crying spells in which emotional expression is altogether out of proportion to the exciting cause. The severe ones, having some resemblance to epileptic convulsions, are called hystero-epileptic attacks. The features of a true epileptic attack are a single peculiar cry; a fall, regardless of circumstances; tonic spasm, in which the tongue is often bitten; with cyanosis and dilated pupils, followed by clonic spasm, with frothing at the mouth, ending in general relaxation and a return of consciousness. The attack occurs suddenly with only a very brief warning, if any, and ends spontaneously in a few minutes. During the seizure the patient never utters a sound, except the initial cry, and the movements have absolutely no appearance of purpose. In the hystero-epileptic attack, on the other hand, there is often an emotional cause and a long premonitory stage, gradually working up to the fall and apparent loss of consciousness; the movements, such as arching the back, struggling or throwing the limbs about, indicate a purpose, though often a grotesque one; the attack may last a long time and be repeatedly renewed; the tongue is not bitten, though the lower lip may be; the patient often screams or talks during the attack; unconscious evacuations never occur.

In severe cases the state between the paroxysms may be marked by highly characteristic symptoms known as hysterical stigmata. The most important of these are hemi-anesthesia, anesthesia whose distribution has no relation to the nerve-trunks or spinal segments, contraction of the visual field, and paralyses and spasms of various muscles without essential symptoms of organic disease.

A diagnosis of hysteria may therefore be based upon:

1. The exclusion of other functional diseases, especially of epilepsy, and of all organic disease.
2. The existence of predisposition.
3. The occurrence of symptoms in response to suggestion.
4. The occurrence of hysterical seizures.
5. The presence of hysterical stigmata.

The negative facts that exclude organic disease and epilepsy are of the first importance, and are

[1] Read before the Colorado State Medical Society, June, 1893.

more essential to the diagnosis than positive symptoms of hysteria; for a patient may have a tumor of the brain, or true epilepsy, and in addition present conspicuous signs of hysteria. Especial care must sometimes be taken to exclude multiple sclerosis, for its symptoms may strongly resemble the hysterical stigmata and be even more changeable.

Case I.—In March, 1893, A. G., twenty-four years of age, a fireman and prize athlete, came under my care. His father had convulsive seizures. The patient has always been unduly affected by a pathetic story or play, and has sometimes wept at the mere thought of a sorrowful occurrence. He is, nevertheless, one of the bravest of men in the line of his duty. A few weeks ago he happened to hear a conversation about heart-failure. When about to fall asleep that night he felt a pain in the cardiac region and was terrified by the idea that his heart might be failing. He broke into a profuse sweat and was unable to sleep, and so he arose and consulted the police-surgeon on duty, who reassured him and gave him a placebo. The next day he was all right until something reminded him of his fright, when he immediately had an attack of palpitation. Since then similar attacks have occurred, always preceded by the same idea. Examination shows absolutely no indication of organic disease of the heart or nervous system. Dr. Johnson informs me that this patient did very well on moral treatment and tonics, but had a decided relapse after seeing two of his comrades killed in a burning building.

The diagnosis was established in this case by the absence of other disease, the evident predisposition, and the marked relation of the alarming symptoms to morbid suggestion.

Case II.—C. B., civil engineer, of robust build, came to me in June, 1892. His family history was good. He had been well until within a year, when he began to use cocain habitually in the nostrils. Two months ago an attack of weakness and numbness of the limbs, dryness of the mouth, and sleeplessness was attributed to cocain-poisoning. About ten days ago the external application of a 10 per cent. solution of cocain to a small boil on the end of the nose was immediately followed by a feeling of great helplessness and fright. Since then he has been much distressed by pain at the back of the head, poor memory, and insomnia. He had just started on a long engineering trip, but on reaching Denver felt so badly that he consulted a physician. Unfortunately, he was told that an attack of apoplexy was impending and that he must not attempt to go on or to return home, for fear of precipitating the stroke. Greatly alarmed, he went to Dr. Bancroft, who kindly sent him to me. As a very careful examination showed no disturbance of circulation and no organic disease of the nervous system, while a strong mental influence was evident, the patient was given some iron and strychnin and assured that he could safely go on his trip if he would only disregard his bad feelings. He did so, and felt perfectly well for eighteen days, during which he successfully accomplished his work. But while returning home he had an alarming spell, in which the heart and respiration seemed to stop. At the same time a boil was found to be forming on the neck. At the first convenient stopping-place he consulted a physician. While the pulse was being taken the hand and arm became numb and felt as though bursting with blood. This sensation quickly spread over the whole body, which then felt as if it were being worked by electricity. I saw him a few days later and again reassured him by saying frankly that his symptoms were hysterical. He again improved, but after a time began to be troubled by sudden glimmering sensations before the eyes, followed by dimness of vision. Many months later he reported that he was about well, very seldom having spells of any kind and always being able to fight them off.

The mental origin of the symptoms was in this case plainly seen in the effect ascribed to the external application of cocain and in the queer feelings coming on while the pulse was being taken. The success of moral treatment confirmed the diagnosis.

Case III.—J. H., thirty-seven years of age, a bartender, came under treatment in January, 1893. His father was asthmatic and his mother was rheumatic. The patient was formerly asthmatic. Seven years ago, while alone on a long drive and very thirsty, he had a peculiar choking spasm of the throat, so that he feared he might die. Similar spasms have recurred ever since, and they occupy the greater part of his attention. Lately he has been having "nervous chills" just as he goes to bed. He complains of various queer sensations, and has a morbid fear of being alone in a small room or on top of a building. He fears he is going to be paralyzed. Careful examination reveals no sign of organic disease. Although the patient says he cannot restrain his spasm of the throat, he can reproduce it at will, and it consists merely of a prolonged swallowing movement with contraction of the platysmæ.

The mental causation of his "spasms" and "chills" was explained to him, and under moral treatment with placebos, he has, for the time at least, recovered.

Case IV.—March, 1893. A. B., aged eighteen years. Some months ago the patient thought he had sprained the right ankle. It was rested and bandaged, but pain continued long after an ordinary sprain would have been well. It was put in plaster, but to no purpose; as soon as an attempt was made to walk the pain returned. Finally he came to Dr. Van Meter, who, believing him to be hysterical, asked me to see him. We found the ankle to be normal in appearance and, when attention was withdrawn, free from pain or tenderness. A confident prognosis was given, and he was instructed to take an increasing amount of exercise every day in absolute disregard of pain. The faradic battery was

used merely for mental effect. In a few weeks the young man was playing foot-ball.

CASE V.—A., twenty-two years of age, supposes that he sprained both ankles some months ago, and has grown steadily worse in spite of treatment. On coming to Denver he placed himself in the care of Dr. Edmundson, who asked me to see him. We found him apparently unable to walk; indeed, he objected to standing for a few moments, saying he would suffer for days from the attempt. He was wearing blue glasses, even in the house, and said that his vision had of late steadily failed. There was a very marked facial twitch, and speech was at times embarrassed. Taking these symptoms superficially, we were both prepared to find a serious organic disease. But on examination the eyes, the various forms of sensibility, the reflexes, and the power to move any of the joints were all found to be normal. On being urged, he was able to stand perfectly well. The facial twitch was found to have existed since childhood, the remnant of an attack of chorea. After a confident prognosis he was treated by Dr. Edmundson with faradism, and graduated exercise in walking. In about six weeks he was able to walk four hours every day.

The two preceding cases are not examples of traumatic neurosis, because there was really no trauma. The following case is a good example of severe injury developing hystero-epilepsy in a somewhat predisposed person.

CASE VI.—J. B., forty-five years old, was of neurotic taint on the mother's side. The patient was a steady drinker, and had been rather "fast" from youth up, though an industrious and successful business man. When thirty years old the right forearm was crushed between cars, necessitating amputation near the elbow. A few weeks after the operation the patient had a violent convulsion, in which a great effort was required to hold him. Similar attacks recurred for many years, at first every few days, later at much longer intervals. Men were often called to hold him, and the more he was held the worse the attack became. Any annoying occurrence, even the sight of a person he disliked, would precipitate an attack. A drink of whiskey would sometimes prevent an impending attack. This patient is now neurasthenic, and sometimes has hysterical attacks of a mild type. When suddenly startled, as by a horse rearing in the street, he experiences a sudden stab of pain in the lumbar region.

CASE VII.—J. I., a locomotive fireman, twenty-seven years of age, whose mother's sister had convulsive seizures. His ill-health dates from failure to pass examination for promotion to engineer four years ago. In the winter of 1889–90, while hunting, he was taken with "chills" and general spasms, the head being thrown back and the spine arched. One attack closely followed another for a considerable time, and he begged his companions to kill him, saying he would rather die than live as he was. Afterward he had no recollection of saying anything. After resuming work, nine months later, he felt perfectly well for a time, but evidently had the idea that his work was bad for him. A few months ago he stopped work, and for a month past has scarcely been able to walk. He thinks he has spinal paralysis.

He is of strong muscular development; he walks with his knees rigidly semi-flexed and the ankles rigid and partly extended. He cannot extend either knee or flex the ankles; when he attempts to do so the opposing muscles strongly contract, and either hold the joint immovable or even move it a little in the opposite direction. The knee-jerks are normal. The patient is greatly startled on having them tested, saying that it goes clear through to his back. There is no ankle-clonus. Electric reactions of muscles are normal. He makes as much ado over the very mild electric tests as some men would over the amputation of a finger. The special senses and general sensibility are normal, except that there is an oval patch on the outside of each leg where the pain-sense is blunted. This analgesia is quickly removed by the faradic brush, but again returns. Urination is always normal.

The diagnosis of hysteria is based on the emotional disturbance at the beginning of the illness, the hysterical nature of the attack appearing soon afterward; the normal condition of the tendon-reflexes and the bladder (excluding lateral sclerosis and myelitis); the contraction of opposing muscles on attempting movement, and finally, the markedly hysteric demeanor. During the short time the patient could stay in the city treatment was successful in restoring normal motion to the knees, but the ankles were not improved. Could I have had this patient long enough I would have put him to bed for a short time and then have made him gradually begin to walk again, using electricity and massage for mental effect.

A very unfavorable factor in the prognosis is his interest in getting $1500 from his brotherhood, on the ground that he is totally disabled for his work as fireman.

CASE VIII.—Z. G., a merchant, twenty-three years of age; a Mexican by descent; has a good family history. Hystero-epileptic convulsions began at the age of sixteen while overworked at school. After apparent recovery the attacks recurred in the winter of 1888–89, and again in March, 1892. Dr. McGarvey, the family physician, describes the seizures as lasting an hour or more, and as marked by the most violent and grotesque contortions, accompanied by exclamations of "Oh, my back!" "Oh, my head!" etc. The patient says that before the attack eyes, head and spine all ache together, and that he afterward does not remember what he has said or done.

He is thirty pounds below his customary weight. There is no paralysis or ataxia and no marked tremor except of the eyelids. Sensibility to touch, pain, and temperature, is good everywhere except that touch is dulled in the left hand. Taste and

smell are normal. Hearing is impaired by otitis media.

There is a remarkable visual defect. Owing to spasm of the internal recti he wears a ten-degree prism, base outward, before each eye, and nothing less will suffice. Testing each eye separately, vision with the prism is normal; without it, less than 4/50.

The use of prisms also markedly affects the visual fields. Without a glass each field is enormously contracted. With a prism the field is greatly increased in extent, especially laterally. Prisms are ordinarly useful only in binocular vision. There is no optical reason for their increasing either the acuity of vision or the extent of the field. This anomalous effect, which was repeatedly verified both by Dr. Coover and myself, must be attributed to suggestion.

The patient would not submit to the rest-cure, which I advised, and he soon passed from my care. Dr. Coover operated on the eye-muscles with excellent temporary effect on the nervous condition. I have just learned, however, that the attacks have returned, and that since the last one there have been maniacal symptoms.

CASE IX.—E. H., thirty-two years of age, came under treatment in April, 1891. His father's mother and two of his father's sisters were insane. A half-sister by the same father is epileptic. The patient has always been sickly and liable to headaches. When sixteen years old, while out of school on account of headaches, he fell in running up stairs. He says he became unconscious and was afterward in bed for several weeks. The whole right side of the body was numbed; hearing on the right side was impaired, and there is said to have been some defect of speech. He could move the right arm and leg, but could not hold objects in the right hand. In a few months he apparently recovered, and for a number of years afterward earned his living as a bookkeeper, writing with his right hand.

At the age of twenty-six he one morning found himself unable to talk; he knew what he wanted to say and wrote it down, but could not utter a word. During the next four months he regained only a few words, and so he submitted to an operation by a distinguished physician of New York, who assured him that it would restore speech.

On recovering from the ether he was able to talk. There was no external wound and no soreness, and he did not know what had been done. A couple of months after the "operation" he had a convulsion, preceded for an hour or more by a sensation as of something crawling in the larynx. Similar attacks occurred at intervals of a few weeks for the next three years. He was then free from them during a residence of more than a year in Colorado. On going to California in January, 1890, the attacks returned and have recurred ever since. Three months ago he broke down from nervous prostration attributed to overwork.

The right arm and leg are distinctly weaker than the left, but the face is not affected. Tremor occurs on moving the right arm or leg, and the movements are decidedly ataxic. Attempting to stand with his eyes closed the patient falls to the right. The knee-jerks are exaggerated, especially the right, but there is no ankle clonus. Sensibility to touch, pain, and temperature, is greatly diminished on the entire right side, including the face and scalp, the boundary being sharply fixed in the median line. Hearing: left, 35/60; right, 8/60, with corresponding loss of bone-conduction. Smell and taste absent on right side. Vision (April 10th): left, 5/15; right, 5/25. The right field is greatly contracted, the color-fields being in their normal relation, but the green lying wholly to the left of fixation. The left field, though larger, is much contracted and the red lies within the green. For about 18° around fixation there is an area in which all objects are said to be blurred.

Three weeks later (May 2d), vision is found to have nearly doubled in each eye, yet the fields are of less than half their former diameters, and the scotoma in the left field has shrunk in proportion. The ophthalmoscope shows the eye-grounds to be normal. There is no nystagmus.

After one of the convulsive attacks, in which the mouth was bloody, I found a wound of the lower lip, but none of the tongue.

The late Dr. Wicks witnessed some of the attacks and gave me an imitation of one. The patient first walked the floor, rubbing his hands together and constantly growing more excited. There was some twitching of the hands, especially the right. After a time he uttered a cry and suddenly threw himself forward upon the floor, where he lay for a few moments perfectly limp. Then he jerked the right hand about and kicked with the right leg. The head was now drawn back and the teeth clenched. There was no frothing or biting and no cyanosis. The movements, which had every appearance of being voluntary, nearly ceased several times and then started up again. The attack lasted many minutes. Finally, the patient was aroused and he then complained of numbness in the right leg, which he kept kicking about in order to restore sensation. He gradually returned to his usual condition and showed no disposition to sleep.

It became very evident that under repeated examination by myself and others the patient was steadily growing worse. I did not have charge of him long enough to carry out any plan of treatment.

The diagnosis in this case was made only after considerable study. The intention-tremor at first suggested multiple sclerosis. But there was nothing else characteristic of sclerosis, and the tremor of hysteria may be exactly like typical intention-tremor. Moreover, a diagnosis of multiple sclerosis, even if established, could not account for all of the phenomena.

The apparent hemiplegia, with hemi-anesthesia and loss of smell, taste, and hearing, on the same side, suggested the possibility of an apopletic lesion of the internal capsule at the time of the fall on the stairs. Against this are several weighty considerations. His age at that time was very unfavorable

to any form of apoplexy, while the paralysis of arm and leg, without involving face or tongue, is highly characteristic of hysteria. Hemi-anesthesia, while quite possible as a result of a capsular lesion, is, taken by itself, more likely to be hysterical, and the fact that the visual defect is not hemianopsia proves conclusively that the sensory part of the capsule has not been destroyed.

On the other hand, positive proofs of the existence of hysteria are abundant. The loss of speech must have been hysterical, for the patient wrote what he wanted to say, while in genuine aphasia, either motor or sensory, writing suffers at least as much as utterance; a sudden lesion of the bulbar nuclei, without other symptoms, is out of the question, and prompt recovery under a sham operation could occur only in hysteria. The contraction of the visual fields is such as occurs in hysteria. The inclusion of the red field by the green never occurs, as far as I know, from any organic disease. It is rare in the hysteria of Americans, but comparatively common in France. The marked shrinking of the fields and of the partial scotoma, while the acuity of vision increased, is utterly inexplicable except as an hysterical freak.

Finally, aside from many minor facts in the demeanor of the patient which pointed to hysteria, there can be no doubt that the attacks witnessed by Dr. Wicks were hysterical.

In considering all of these cases taken together, I see no essential difference between hysteria in men and hysteria in women. It may be that there is less of a craving for fuss and sympathy in men than in women, but in its large features the disease appears to be the same in both sexes.

ON THE INCREASING PREVALENCE OF SCABIES.[1]

BY HENRY W. STELWAGON, M.D.,
CLINICAL PROFESSOR OF DERMATOLOGY IN THE JEFFERSON MEDICAL COLLEGE; DERMATOLOGIST TO THE PHILADELPHIA HOSPITAL, ETC.

UNDER the foregoing title Dr. James C. White, several years ago, called the attention of the profession to the increasing frequency of this disease, especially with reference to his own city, Boston.[2] The same tendency had been observed by me for several years previously in Philadelphia, and had, indeed, been so striking that at that very time a greater part of the data here presented was prepared for publication. Since then the proportion has kept its high place, and has, upon the whole, with slight fluctuation, been steadily growing, so that at the present time in the dispensary practice of this city the itch constitutes 10 to 15 per cent. of all skin cases. The following table (Table I) summarizes my own observations at the various services for skin disease with which I am or have been connected:

TABLE I.—SHOWING THE INCREASING PREVALENCE OF SCABIES IN PHILADELPHIA.

		1880	1881	1882	1883	1884	1885	1886	1887	1888	1889	1890	1891	1892
Philadelphia Disp. for Skin Diseases	No. patients	217	308	331	279	239	388	277	433	642	688	451	...	...
	Scabies	8	5	9	3	11	14	20	48	100	66	52	...	...
	Percentage	3.69	1.62	2.72	1.07	4.6	3.61	7.22	11.09	15.58	9.59	11.53	...	...
Northern Disp., Skin Service	No. patients	440	464	460	538	405	...	...	...	...	...	...	495	500
	Scabies	3	10	13	16	16	...	...	...	...	...	...	64	61
	Percentage	0.68	2.15	2.83	2.97	3.95	...	...	...	...	...	...	12.93	12 2
University Hosp., Skin Dispensary	No. patients	...	...	...	...	448	402	396	515	433	435	...	...	...
	Scabies	...	...	...	...	3	13	13	24	38	28	...	...	...
	Percentage	...	...	...	...	0.67	3.23	3.3	4.66	8.77	6.44	...	...	...
Philadelphia Hosp. Skin Ward	No. patients	...	...	...	...	...	...	...	77	110	103	180	163	152
	Scabies	...	...	...	...	...	...	...	9	18	15	11	11	12
	Percentage	...	...	...	...	...	...	...	11.7	16.36	14.56	6.11	6.75	7.89
Howard Hospital, Skin Dispensary	No. patients	...	...	...	...	...	...	...	...	241	182	213	295	149
	Scabies	...	...	...	...	...	...	...	...	12	29	6	39	18
	Percentage	...	...	...	...	...	...	...	...	4.98	15.93	2.82	13.22	12.08
Jefferson Hospital, Skin Dispensary	No. patients	...	...	...	...	...	...	...	...	...	...	438	841	538
	Scabies	...	...	...	...	...	...	...	...	...	...	37	146	90
	Percentage	...	...	...	...	...	...	...	...	...	...	8.45	17.36	16.73
Totals	No. patients	657	772	791	817	1092	790	673	1025	1425	1408	1282	1794	1339
	Scabies	11	15	22	19	30	27	33	81	168	138	106	260	181
	Percentage	1.67	1.94	2.78	2.32	2.75	3.42	4.9	7.9	11.77	9.8	8.27	14.49	13.52

It will be clearly seen by a glance at this table that scabies is becoming a common disease among the poor, and that it is not limited to particular parts of the city, although it is, it is true, much more
